Several monoclonal antibodies have been produced against *P. chrysanthemi* strains that can be used for detection or identification by double–antibody sandwich (DAS)-ELISA with a sensitivity of 5×10^3 CFU/ml in carnation stem samples (Nassar et al., 1996b), time-resolved fluoroimmunoassay (TR-FIA) in potato peel extracts with a sensitivity of 10^5 cells/ml (Van De Wolf, 1993).

L-Asparaginase from *P. chrysanthemi* provides an alternative to the enzyme from *E. coli* for the effective treatment of acute lymphoblastic leukemia (Goward et al., 1992). It alters the coagulation system less severely than does *E. coli* asparaginase (Carlsson et al., 1995).

Causes vascular wilts, stunting, soft rots, spotting of leaves or parenchymal necroses of a wide range of plant species and cultivars like *Allium cepa, Capsicum anuum*, *Colocasia esculanta*, *Kalanchoe blossfeldiana*, *Nicotiana tabacum*, *Nopalea* sp., *Pelargonium zonale*, and *Primula* sp. The disease symptoms are usually systemic.

The mol% G + C of the DNA is: 55.1–57.1 (T_m, Bd).

Type strain: ATCC 11663, DSM 4610, LMG 2804, ICMP 5703, NCPPB 402.

GenBank accession number (16S rRNA): U80200, Z96093.

4. **Pectobacterium cypripedii** (Hori 1911) Brenner, Steigerwalt, Miklos and Fanning 1973b, 205[AL] emend. Hauben, Moore, Vauterin, Steenackers, Mergaert, Verdonck and Swings 1999a, 1 (*Erwinia carotovora* biovar cypripedii (Hori 1911) Dye 1969a, 93; *Erwinia cypripedii* (Hori 1911) Bergey, Harrison, Breed, Hammer and Huntoon 1923, 171; *Bacillus cypripedii* Hori 1911, 91.)
cyp.ri.ped′i.i. M.L. n. *Cypripedium* generic name; M.L. gen. n. *cypripedii* of cypripedium orchids.

The characteristics are as described for the genus and as listed in Tables BXII.γ.241 and BXII.γ.242. The gene cluster encoding three subunits of membrane-bound gluconate dehydrogenase (GADH) was studied by Yum et al. (1997). Causes a brown rot of cypripedium orchids (*Cypripedium* spp.). The disease usually attacks orchids with fleshy leaves. It starts with small water-soaked lesions that enlarge and become slightly sunken, brownish greasy-looking areas. It may spread down the stem and involve the growing point.

The mol% G + C of the DNA is: 54.1–54.6 (T_m, Bd).

Type strain: ATCC 29267, DSM 3873, ICMP 1591, LMG 2657.

GenBank accession number (16S rRNA): U80201, Z96094.

Genus XXV. ***Candidatus*** **Phlomobacter** *Zreik, Bové and Garnier 1998, 260*

MONIQUE GARNIER

Phlo.mo.bac.ter. Gr. n. *phlomos* bark; Gr. n. *bakterion* a small rod; M.L. neut. *Phlomobacter* rod in the bark.

Filamentous bacteria occurring in the sieve tubes of phloem tissue of plants (Figs. BXII.γ.202 and BXII.γ.203). The original description is from infected strawberry plants (*Fragaria* x *ananassa*) showing leaf marginal chlorosis and stunting in France (Nourrisseau et al., 1993). Like most other phloem-restricted bacteria, *Candidatus* Phlomobacter fragariae has resisted *in vitro* cultivation.

The mol% G + C of the DNA is: not determined.

Type species: *Candidatus* Phlomobacter fragariae Zreik, Bové and Garnier 1998, 260.

FURTHER DESCRIPTIVE INFORMATION

Phylogenetic treatment Phylogenetic analysis of the 16S rRNA gene indicates that *Candidatus* Phlomobacter is a member of the *Enterobacteriaceae* in the *Gammaproteobacteria*. Its closest cultured relative is *Arsenophonus nasoniae*, the recently characterized agent of the son-killer trait in the parasitic wasp *Nasonia vitripennis* (92% 16S rDNA identity) (Fig. BXII.γ.204). The complete sequence of *Candidatus* Phlomobacter 16S rRNA gene is deposited in GenBank under the accession number U91515. The oligo-

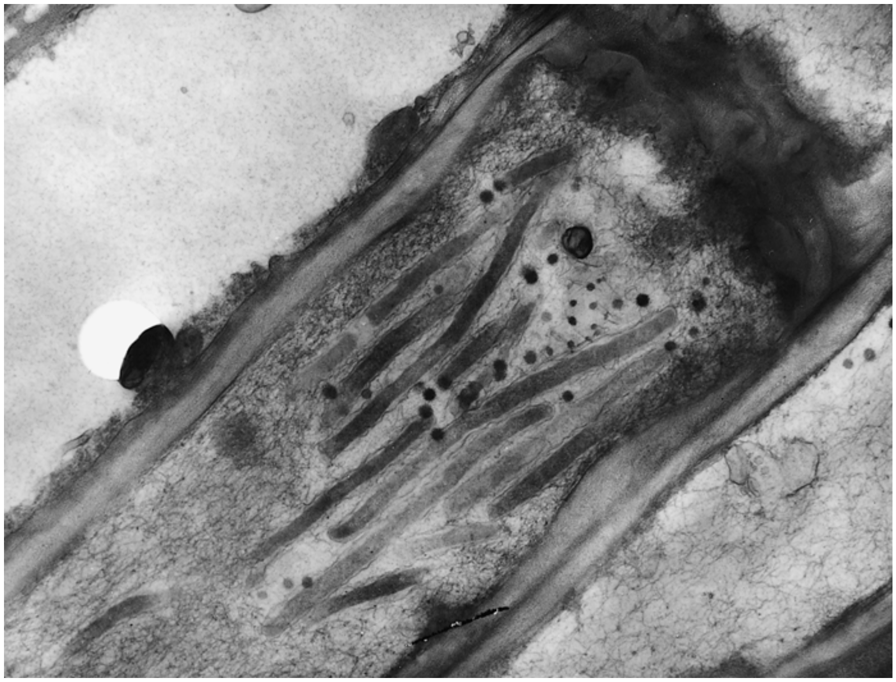

FIGURE BXII.γ.202. *Candidatus* Phlomobacter fragariae cells in a phloem sieve tube of strawberry leaves showing marginal chlorosis (× 20,000).

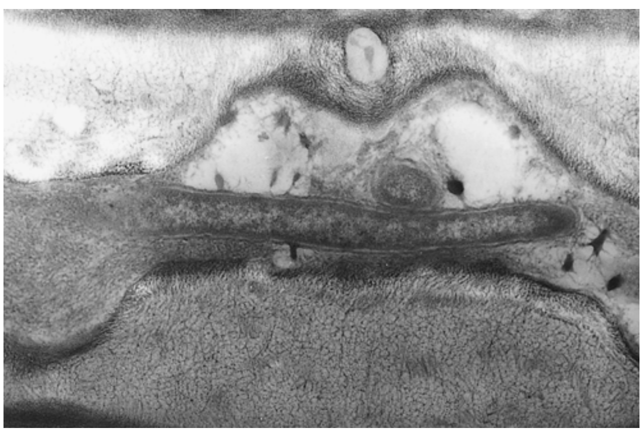

FIGURE BXII.γ.203. *Candidatus* Phlomobacter fragariae cell in a sieve tube with thickened walls (× 29,000).

nucleotide sequence complementary to unique region of the 16S rRNA is 5′-AGCAATTGACATTAGCGA-3′ (Zreik et al., 1998).

Cultivation To date, all attempts to culture *Candidatus* Phlomobacter have failed.

Strain morphology Electron microscopy measurements on thin sections show that *Candidatus* Phlomobacter fragariae cells are 0.2–0.27 μm in diameter and up to 4 μm in length. The cell envelope is 250 nm thick. There is no evidence for flagella or pili (Figs. BXII.γ.202 and BXII.γ.203).

Ecological data, host range *Candidatus* Phlomobacter are phytopathogenic bacteria affecting strawberry (*Fragaria* x *ananassa*) cultivars in which they induce marginal chlorosis of leaf blades, stunting, and fruit malformations. At the ultrastructural level, they induce thickening of the sieve tube walls (Fig. BXII.γ.203). To date, they have not been described in other hosts, and trials to transmit the bacterium via dodder (*Cuscuta campestris*) to periwinkle (*Catharantus roseus*), the experimental plant for phloem-restricted bacteria, have failed. Vector transmission of the bacterium occurs in nature. The insect vector has been identified as *Cixius wagneri* (China). The disease was described in France, and its incidence is highest in strawberry production fields in Southern France. Strawberry nurseries, located in northern France, are not affected. Whether *Candidatus* Phlomobacter fragariae is present in countries other than France has not been investigated.

Procedures for Testing Special Characters

Specific identification *Candidatus* Phlomobacter can be identified by amplification and sequencing of the 16S rDNA. By sequence comparisons, two primers specific for phlomobacteria have been selected on the 16S rDNA sequence. They are efficient and specific for *Candidatus* Phlomobacter detection in plants. When used for DNA amplification in insects, these primers are not specific, as *Candidatus* Phlomobacter shares strong homologies with insect bacterial symbionts and parasites as well as with enterobacteria. Thus, specific identification from hosts other than plants requires sequencing of the 16S rDNA. Genes other than 16S rDNA have been isolated and are under study.

Acknowledgments

Monique Garnier-Semancik died suddenly in May, 2003. She was Director of Research at INRA Bordeaux and served as director of a "Joined Research Unit" in which INRA researchers and University teachers work together. Most of her scientific contributions were to the field of phloem- and xylem-restricted plant pathogenic bacteria, which won her respect both in France and internationally.

List of species of the genus Candidatus Phlomobacter

1. *Candidatus* Phlomobacter fragariae Zreik, Bové and Garnier 1998, 260.
   fra.ga' riae. L. gen. n. *fragaria, fragariae* of *fragaria*, strawberry.

   The description of this organism is identical to that of the genus *Candidatus* Phlomobacter.

   The mol% G + C of the DNA is: not determined.
   GenBank accession number (16S rRNA): U91515.

Genus XXVI. **Photorhabdus** *Boemare, Akhurst and Mourant 1993, 253*^{VP}

Noël E. Boemare and Raymond J. Akhurst

Pho.to.rhab' dus. Gr. n. *photo* light; Gr. fem. n. *rhabdus* rod; M.L. masc. n. *Photorhabdus* bioluminescent rod-shaped bacterium.

Asporogenous rod-shaped cells 0.5–2 × 1–10 µm. Cell size is highly variable within and between cultures with occasional filaments up to 30 µm long. In the last stage of exponential growth and during stationary growth period, **spheroplasts may occur with an average of 2.6 µm in diameter** (10–20% of cell population), resulting from the partial disintegration of the cell wall. Proteinaceous **protoplasmic inclusions** are synthesized inside a high proportion of cells (50–80%) during the stationary period. Gram negative, motile by means of peritrichous flagella. Facultatively anaerobic, having both a respiratory and a fermentative type of metabolism. Optimum growth temperature usually ~28°C; some strains grow at 37–38°C. Most strains produce pink, red, orange, yellow, or green **pigmented colonies on nutrient agar, and especially on rich media** (tryptic soy agar, egg yolk agar). Bioluminescent, usually detectable by the dark-adapted eye; intensity varies within and between isolates and may only be detectable by photometer or scintillation counter in some isolates; only very few nonluminescent isolates have been reported. **Spontaneous phase shift occurs in subcultures inducing the appearance of phase II clones** characterized by the loss of neutral

red adsorption on MacConkey agar, of production of antibiotics, and of some other properties usually exhibited by wild clones freshly isolated from the natural environment and named phase I variants. Catalase positive. **Do not reduce nitrate.** Negative for oxidase, O-nitrophenyl-β-D-galactopyranoside (ONPG), Voges–Proskauer, arginine dihydrolase, lysine and ornithine decarboxylase tests. Proteolytic for gelatin. Most strains hemolytic for sheep and/or horse blood, some producing an unusual annular hemolysis on sheep blood at 25°C (Fig. BXII.γ.205). Lipolytic activity on Tween 20; many strains lipolytic for Tweens 40, 60, 80, and/or 85. Acid production from glucose without gas. Acid produced from fructose, D-mannose, maltose, ribose, and *N*-acetylglucosamine; weak for acid production from glycerol. Fumarate, glucosamine, L-glutamate, L-malate, L-proline, succinate, and L-tyrosine are utilized as sole carbon and energy sources. Biochemical identification of *Photorhabdus* within the family *Enterobacteriaceae* is summarized in Table BXII.γ.245. Sequence analyses of 16S rDNA show that all *Photorhabdus* strains branch deeply within the radiation of the family *Enterobacteriaceae*, and have **a specific TGAAAG sequence at positions 208–213** (*E. coli* numbering). **The natural habitat for most strains is the intestinal lumen of entomopathogenic nematodes of the genus** *Heterorhabditis* and insects infected by these nematodes. However, some nonsymbiotic strains have been identified as opportunistic pathogens for humans, not nematodes.

The mol% G + C of the DNA is: 43–45.

Type species: **Photorhabdus luminescens** (Thomas and Poinar 1979) Boemare, Akhurst and Mourant 1993, 254 *Xenorhabdus luminescens* Thomas and Poinar 1979, 354.)

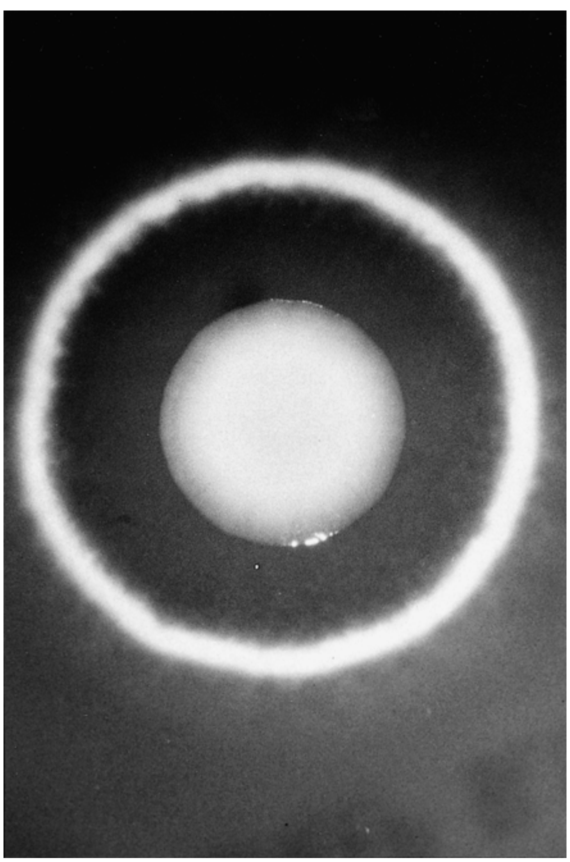

FIGURE BXII.γ.205. Annular hemolysis on sheep blood (10%) agar produced at 25°C by many *Photorhabdus* strains.

FURTHER DESCRIPTIVE INFORMATION

The strains formerly considered as belonging to *Xenorhabdus luminescens* clearly form a DNA relatedness group that is distinct from all the other *Xenorhabdus* strains (Boemare et al., 1993; Akhurst et al., 1996). These DNA data, together with the significant differences in phenotypic characters between *"X. luminescens"* and the other *Xenorhabdus* species (Akhurst and Boemare, 1988; Boemare and Akhurst, 1988), fatty acids of the whole cellular composition (Janse and Smits, 1990), and chemotaxonomic data (Suzuki et al., 1990), led to the transfer of *X. luminescens* into a new genus, *Photorhabdus*, as *Photorhabdus luminescens* comb. nov. (Boemare et al., 1993). Table BXII.γ.245 lists the characteristics of *Photorhabdus* genus for the three species and four subspecies recognized today (Fischer-Le Saux et al., 1999).

Nevertheless, comparison of 16S rDNA sequences of the type strains of *Photorhabdus* and *Xenorhabdus* species indicate the close phylogenetic relationship of these two genera (Rainey et al., 1995). However, all *Xenorhabdus* strains could be clearly distinguished from strains of *Photorhabdus* by the occurrence of a TTCG sequence at positions 208–211 (*E. coli* numbering) of the 16S rDNA, while *Photorhabdus* have a TGAAAG sequence (Szállás et al., 1997). The nearest phylogenetic neighbor is *Proteus vulgaris* as demonstrated by PCR-RFLP (Brunel et al., 1997) and sequencing of 16S rDNA (Rainey et al., 1995; Suzuki et al., 1996; Szállás et al., 1997; Fischer-Le Saux et al., 1999).

The major cellular fatty acids of *Photorhabdus* are $C_{16:0}$ and $C_{18:1}$; $C_{15:0\ iso}$, $C_{17:0\ iso}$, and $C_{16:1}$ are major components in some strains (Janse and Smits, 1990; Suzuki et al., 1990). Ubiquinone-8 is the respiratory quinone in all strains (Suzuki et al., 1990).

The main difficulty when subculturing *Photorhabdus* strains is the occurrence of a colonial dimorphism that appears suddenly on agar plates. It can be easily detected by two major properties: dye adsorption and antibiotic production (Akhurst, 1980). Each strain occurs as two phase variants that can be described as morphovar, chemovar, and/or biovar. The bacterium isolated from the infective stage (*dauer* larvae) of *Heterorhabditis* was named the phase I variant (Boemare and Akhurst, 1988). Phase I colonies are mucoid and stick to the loop when streaked on plates, produce antibiotic molecules (Akhurst, 1982a), adsorb dyes when incorporated into agar (e.g., the neutral red in MacConkey agar), and are differently pigmented from phase II variants (e.g., red in phase I and yellow in phase II). Among the *Enterobacteriaceae*, cells of some strains of *Photorhabdus* may be the largest known (0.5–2 × 1–10 μm). Phase I cells are larger than phase II cells; they are pleomorphic, comprising rods (80–90%) and spheroplasts (10–20%), and harbor protoplasmic inclusions (Boemare et al., 1983) (Fig. BXII.γ.206). Phase II appears spontaneously during stationary growth period from *in vitro* culture and during nematode rearing on artificial diets. Phase II colonies are not mucoid, do not adsorb dye, and do not produce antibiotics. Several intermediate colony forms, possessing at least some phase I properties, have been recorded (Gerritsen et al., 1992); however, it is not certain that these are not mixtures of phase I and phase II. In general, variation in phase-related characters has been reported qualitatively ("+" and "−"). However, for every character that can be quantified (e.g., luminescence, antibiotic production), it is clear that the difference between phases is a matter of magnitude, not presence/absence. It is highly probable that this holds true for all phase-related characters. Table BXII.γ.246

[e]Type strain ATCC 43950 isolated from human blood and/or wounds.

[f]Type strain CIP 105563 isolated from *Heterorhabditis megidis* Palaearctic group.

summarizes the characters affected by phase variation. However, both phases show a similar entomopathogenic effect and share all the other bacteriological properties of members of the genus.

In natural conditions, cells of *Photorhabdus* are carried in the intestinal lumen of the free-living stage (infective juvenile L3 or *dauer* larva) of *Heterorhabditis*. The bacterial cells are stored and do not multiply in the gut of the *dauer* host, which is a non-feeding stage. When infective juveniles infect an insect, they release their symbionts into the body cavity of the insect prey. *Photorhabdus* cells multiply inducing toxemia and septicemia and the insect dies. The carcass is a sort of monoxenic microcosm where the symbionts eliminate competitive microorganisms by using several antimicrobial barriers, such as antibiotics possessing a wide spectrum of activity (Akhurst, 1982a) and bacteriocins acting against closely related species (Boemare et al., 1992; Baghdiguian et al., 1993). Nematodes reproduce in the insect carcass, feeding on the insect remains metabolized by the symbiotic bacteria and on the bacterial biomass. When the *dauers* escape the insect cadaver to search for new prey, they carry the symbiont in their gut, ensuring the vertical transmission of the mutualistic association. Although the nematode hosts are the natural vectors of their propagation in the insects, in nutritional terms *Photorhabdus* might be considered entomophilic rather than nematophilic microorganisms.

The life cycle of the clinical strains of *Photorhabdus* is much less certain. *Photorhabdus* has been isolated from five clinical sources in the U.S.A. (Farmer et al., 1989) and six recently in Australia (Peel et al., 1999; Gerrard et al., 2003). Isolations were variously made from tissue, blood, and sputum samples; no definite route of infection has been established. Although some patients may have been immunocompromised, this was definitely not the case for at least two of the Australian patients. These clinical isolates were all easily cultured on standard media at 37°C. They all exhibited the annular hemolysis on sheep blood agar at 25°C. By the time they were identified, all were phase II cultures; it is not known if that is the form in which they were originally isolated.

In vitro subcultures from fresh isolates can be obtained without major difficulties. *Photorhabdus* are mesophilic bacteria able to grow between 15 and 35°C, and some strains at 37–38°C. Subculturing and all biochemical tests should be undertaken around the optimal temperature at 28°C. Usually, nutrient agar or Luria-Bertani agar are sufficient for growth. On minimal media, nicotinic acid, *para*-aminobenzoic acid, proline, tyrosine, and serine are required as growth factors, the mix of growth factors varying between strains (Grimont et al., 1984b). Minimal medium II (BioMérieux) contains all the necessary requirements to test utilization of organic compounds.

Although the shift from phase I to phase II is spontaneous, it is remarkable that the wild *dauer Heterorhabditis* almost exclusively harbor phase I *Photorhabdus* (Akhurst and Boemare, 1990). The role of phase II variants is not clarified, and today we have no convincing data to support a good explanation of their occurrence. Phase change occurs during the *in vitro* stationary period in a highly unpredictable manner (Akhurst and Boemare, 1990). The two phases of *Photorhabdus* differ significantly in respiratory activity (Smigielski et al., 1994). After periods of starvation, phase II cells recommenced growth within 2–4 h after the addition of nutrients, compared with 14 h for phase I cells, indicating a more efficient nutrient uptake ability in the former.

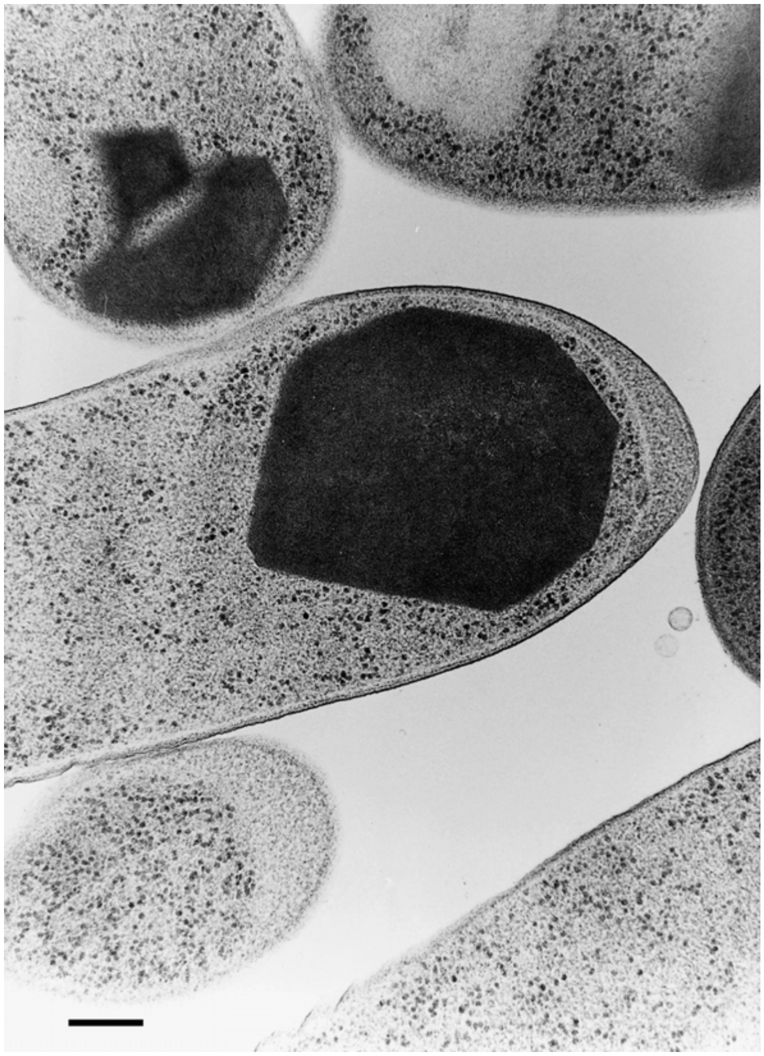

FIGURE BXII.γ.206. Electron micrograph of a fast-freeze fixation and freeze substitution of a culture on nutrient agar in stationary growth of the type strain ATCC 29304 of *Photorhabdus* showing typical inclusions in the protoplasm of the cells. Sections were contrasted with uranyl acetate and lead citrate. Bar = 0.5 μm.

TABLE BXII.γ.246. Differential characteristics of phase variants in *Photorhabdus*[a,b]

Characteristic	Phase I	Phase II
Colonies	mucoid	smooth
Colonial adhesiveness	+	−
Dye adsorption	+	−
Pigmentation	+	+[c]
Protoplasmic inclusions	+	[−] w
Bioluminescence	+	+ w
Antibiotic production	+	−
Lecithinase (egg yolk agar)	+	−

[a]Symbols: +, 90–100% of strains are positive; [−], 11–25% are positive; −, 0–10% are positive. The letter w indicates a weak reaction. All tests were done at 28° ± 1°C.

[b]Characteristics scored in this table are those that always differ between phases, but there are others that differ for the two phases of an individual strain. For those characteristics that can be quantified (e.g., bioluminescence, pigmentation, and protoplasmic inclusions), the difference between phases is a matter of magnitude, not presence/absence. It is highly probable that this holds true for all phase-related characteristics.

[c]Phase II variants of *Photorhabdus* are differently pigmented from phase I variants (e.g., colonies of strain K80 are red in phase I, and yellow in phase II).

Phase II variants may grow a little on complex media previously utilized by phase I variants (Akhurst and Boemare, 1990). However, although reciprocal phase change occurs in *Xenorhabdus*, conversion from phase II *Photorhabdus* to phase I has not been unambiguously demonstrated.

A DNA relatedness study demonstrated unequivocally that phase variation of *Photorhabdus* is a real phenomenon, and not merely an artifact due to contamination, by showing that the two phases of any strain have 100% DNA relatedness. Furthermore, restriction digests and Southern cross analysis of phase I and phase II DNA indicate that the organization of the genome is the same in the two phases (Akhurst et al., 1992).

There are several groups and subgroups within the *Photorhabdus* strains associated with nematodes (*Heterorhabditis* spp.) and human clinical specimens. By using the hydroxyapatite (HA) method to analyze DNA–DNA *Photorhabdus* heteroduplexes, two DNA relatedness groups associated with nematode (*Heterorhabditis* spp.) and another that contains the American human clinical specimens (Farmer et al., 1989) were recognized (Akhurst et al., 1996). More recently, restriction patterns obtained after amplification of the 16S rDNA allowed identification of 12 genotypes

among *Photorhabdus* strains (Fischer-Le Saux et al., 1998). By hybridizing the DNA of some representative strains of each ribosomal genotype, and by using the S1 nuclease method, the previous three genomic groups were confirmed (Fischer-Le Saux et al., 1999). They exhibited between them DNA–DNA hybridization values lower than 42% with $\Delta\ T_m$ higher than 8.7°C. Moreover, the phylogenetic trees inferred from the complete 16S rDNA sequence analysis (neighbor joining, parsimony, and maximum likelihood) delineate the same clusters as both DNA–DNA hybridization methods. Consequently, species and subspecies among *Photorhabdus* were delineated by applying a polyphasic approach, combining 16S rDNA, DNA–DNA hybridization, and phenotypic data (Fischer-Le Saux et al., 1999) (Table BXII.γ.245). Based on DNA–DNA hybridization, 16S rDNA and *gyrB* sequencing, and phenotypic data, the new Australian clinical strains (Peel et al., 1999) will probably constitute a subspecies of *P. asymbiotica* (Akhurst et al., unpublished data). A nonluminescent strain (Akhurst and Boemare, 1986) probably constitutes yet another species (Akhurst et al., 1996).

Within *P. luminescens*, subgroups of strains, which shared very high DNA–DNA hybridization values and ΔT_m lower than 1.5°C and were separated by stable 16S rDNA branching, were identified (Fischer-Le Saux et al., 1999). Consequently, *P. luminescens* was divided into three subspecies (Table BXII.γ.245).

The molecular mechanism of phase variation is uncertain. Lipase and protease are regulated at a posttranslational level in the Irish K122 strain of *P. temperata* (Wang and Dowds, 1993), whereas the *lux* genes are posttranscriptionally regulated in the Hm strain (Hosseini and Nealson, 1995). This contrasts with *X. nematophila* in which the flagellin genes are not transcribed in phase II (Givaudan et al., 1996). These preliminary studies seem to indicate that phase variation in *Photorhabdus* is regulated at a different genetic level than in *Xenorhabdus*.

Several strains of *Photorhabdus* harbor plasmids for which no role or gene has been identified. Heating cultures at 45°C (20 min) and subculturing at 28°C, or mitomycin C treatment, may lead to complete lysis of the cultures, suggesting the occurrence of lysogenic strains (Boemare et al., 1992). Phage tail-like particles, different from those of *Xenorhabdus*, are associated with bacteriocin production in *Photorhabdus* (Baghdiguian et al., 1993).

Antibiograms (Bauer et al., 1966) must be done at 28°C and incubated for 3 days to observe clear zones. *Photorhabdus* have large zones of inhibition around disks impregnated with nalidixic acid, gentamicin, streptomycin, kanamycin, tetracycline, and chloramphenicol, but none around penicillin. Resistance is variable from strain to strain with colistin, ampicillin, carbenicillin, and cephalothin (Farmer, 1984b). It is interesting to note that one patient infected with an isolate sensitive to gentamicin *in vitro* did not respond to gentamicin treatment (Peel et al., 1999).

All strains of *Photorhabdus* have been reported to be entomopathogenic, the LD_{50} usually being <100 cells when injected into hemocoel of the insect *Galleria mellonella* (Farmer et al., 1989; Akhurst and Boemare, 1990; Akhurst and Dunphy, 1993). *Photorhabdus* has also been isolated from human wounds and blood in the U.S.A. (Farmer et al., 1989) and more recently in Australia (Peel et al., 1999). None of the infections was lethal, but some required weeks of treatment.

Photorhabdus strains are the only terrestrial bioluminescent bacteria known today. Their *lux* genes share a strong identity with the *lux* genes of the marine luminescent *Photobacterium*, and *Vibrio* spp. (Frackman et al., 1990). No satisfactory demonstration has yet been provided to explain the role of luminescence in this genus.

Two ecological niches have been identified for *Photorhabdus*: one as a metabolically active form in the insect host, and the other as a quiescent form in the gut of the nonfeeding dauer nematode. The occurrence of nonsymbiotic clinical strains possessing the phase II properties of the nematophilic symbionts and the remarkable differences in respiratory activity between the two phases of the symbiotic strains suggest that there may be a third niche in the soil. However, experiments to test the symbiotic strains ability to grow and survive in external environments indicate that they disappear within a few days (Morgan et al., 1997). *Photorhabdus* strains may enter into a nonculturable but viable survival strategy, as do *Aeromonas*, *Vibrio*, *E. coli*, and *Salmonella* spp.

The specific interaction with the nematode host has been tested by gnotobiological experiments. These assays demonstrate that *Photorhabdus* isolates do not support culture of any *Steinernema* species *in vitro* (Akhurst, 1983b) but in some combinations support culture of nonhost *Heterorhabditis* spp. (Akhurst and Boemare, 1990; Han et al., 1990). Similarly, *Xenorhabdus* spp. do not support culture of *Heterorhabditis* (Akhurst, 1983b). In all the microbial ecological surveys undertaken, a *Xenorhabdus* isolate has never been recovered from *Heterorhabditis* or a *Photorhabdus* isolate from *Steinernema*. Despite the intestinal location of these bacteria, which would allow environmental contamination, the specificity of *Photorhabdus* for *Heterorhabditis* is a remarkable feature of this symbiosis (Boemare et al., 1997a; Forst et al., 1997). When accurate microbial ecology studies are undertaken, using a simple and fast method of PCR-RFLP of 16S RNA (Brunel et al., 1997), a clear correspondence between *Photorhabdus* isolates and nematode species can be seen. From a total of 75 isolates identified in the Caribbean region (Fischer-Le Saux et al., 1998), two genotypes were associated only with *Heterorhabditis bacteriophora* and another two only with *Heterorhabditis indica*.

Photorhabdus–Heterorhabditis and *Xenorhabdus–Steinernema* symbioses are widely divergent. Similar patterns of infectivity, life cycle, and mutualism with nematodes have to be considered to be the result of evolutionary convergence. The symbiotic, pathogenic, and phase variation properties that are the conditions for such associations (Boemare and Akhurst, 1994) do not necessarily imply the same physiological mechanisms. As more genes are sequenced, it will be possible to formulate a clearer picture to explain the convergent evolution of *Photorhabdus–Heterorhabditis* and *Xenorhabdus–Steinernema* symbioses (Boemare and Akhurst, 1994).

Enrichment and Isolation Procedures

Three methods have been used for isolating *Photorhabdus* from nematodes. The "hanging drop" uses a sterile drop of insect hemolymph to which surface-disinfected dauer stage *Heterorhabditis* are added (Poinar and Thomas, 1966). The nematodes exsheath and commence development, releasing their symbiont, which can be subcultured after about 24 h. A second method is to collect under sterile conditions a drop of insect hemolymph from an insect 24 h after infection by *Heterorhabditis*, and to streak it onto nutrient agar. The third method is to crush about 100 surface-disinfected dauer *Heterorhabditis* that have lost their second stage cuticle and to streak the macerate onto nutrient agar (Akhurst, 1980). This latter method is the most rigorous method for assessing the microflora of the intestine of entomopathogenic

nematodes, provided that a suitable control on the effectiveness of the surface disinfection is employed. It reveals the occurrence of *Photorhabdus* in every *Heterorhabditis* sp.

All isolations from nematodes or infected insects should be conducted at or below 28°C.

Human clinical isolates of *Photorhabdus* have been variously obtained from open wounds, tissues aspirated from unerupted lumps, blood, and sputum. These clinical isolates and those from two subspecies of *P. luminescens* can be cultured at 37–38°C and 38–39°C, respectively (Table BXII.γ.245).

Maintenance Procedures

The standard methods of freeze-drying and low temperature storage (liquid nitrogen or at −80°C) used for *Enterobacteriaceae* are also useful for long-term storage of *Photorhabdus* strains; −20°C is unsatisfactory. Cultures do not survive more than a few months in broth or on agar plates at room temperature, and phase variation is likely to occur in this time. Cultures can be routinely maintained for 1 month at 15°C, but storage at 4°C is unsuitable; to prevent phase variation, phase I clones have to be subcultured every week from the neutral red dye-adsorbing clones on MacConkey agar.

Procedures for Testing Special Characters

With the exception of the test for annular hemolysis, which should be conducted at 25°C, all biochemical tests used for phenotypic characterization of *Photorhabdus* should be conducted at 28°C, its optimal growth temperature.

Details of the techniques for identifying the phase variants have been summarized (Boemare et al., 1997b). Adsorption of dyes as described by Akhurst (1980) is the most convenient test to characterize the phase variants. MacConkey agar, or better still MacConkey agar without the bile salts, is a good medium for distinguishing phase I variants (red colonies) from phase II variants (off-white or yellow) (Boemare and Akhurst, 1988). On the NBTA medium [1] described by Akhurst (1980), the adsorption of bromothymol blue by *Photorhabdus* may be confused by the pigmentation of strains and the resulting color of the clones can be difficult to distinguish. As most *Photorhabdus* are pigmented, growth on nutrient agar is often sufficient to differentiate clones of the variants, which differ significantly in not only pigmentation but also colony morphology, with phase I being mucoid and convex whereas phase II is non-mucoid and flattened.

To test antibiotic production by *Photorhabdus*, clones of both variants are spot-inoculated on nutrient agar plates. After growth (generally 48 h), cultures are killed by chloroform vapor (30 min) and covered by fresh nutrient semisolid agar (0.6%) inoculated with a bacterial indicator such as *Micrococcus luteus* (Akhurst, 1982a). The inhibition halos of the indicator culture indicate the phase I variants.

Bioluminescence for most of phase I variants can be checked in a darkroom after 10 min for dark-adaptation of the eyes. To assess absence or weakness of such a light production in the phase II variants, by comparison with the phase I variants' luminescence, a scintillation counter, a fluorimeter, or a photomultiplier have to be used. A loopful of an agar culture of each phase variant culture is suspended in 10 ml of distilled water in a scintillation vial for immediate counting with a fully opened window setting (Grimont et al., 1984b).

1. NBTA medium: nutrient agar containing 0.0025% (w/v) bromothymol blue and 0.004% (w/v) triphenyltetrazolium chloride (Akhurst, 1980).

Differentiation of the genus *Photorhabdus* from other genera

Photorhabdus strains are easily distinguished phenotypically from all the *Xenorhabdus* spp. Bioluminescence and catalase, both physiologically very significant characters, are positive for *Photorhabdus* and negative for *Xenorhabdus*. In most strains, urease is positive and assimilation of DL-lactate is negative for *Photorhabdus* (Table BXII.γ.245); annular hemolysis on sheep blood agar was only observed with *Photorhabdus* strains (Tables BXII.γ.245 and BXII.γ.247). Bioluminescence does not cause confusion with the light-emitting marine bacteria of different families. *Photorhabdus* is differentiated from *Vibrio*, *Alteromonas*, and *Photobacterium* by having peritrichous, not polar, flagella and in not requiring sodium ions for growth.

Taxonomic Comments

By DNA–DNA hybridization *Photorhabdus* is only 4% related to *Escherichia coli*, the type species of the type genus for the family (Table BXII.γ.245). However, *Photorhabdus* possesses the enterobacterial common antigen (Ramia et al., 1982). These data indicate that, while most biochemical tests used for differentiation of the *Enterobacteriaceae* are negative for *Photorhabdus* and although it is only distantly related to the genera that comprise the "core" of the family (Farmer, 1984b), *Photorhabdus* should be retained in the family *Enterobacteriaceae*.

It appears that the genus *Photorhabdus* evolved after the main radiation of *Xenorhabdus* species occurred (Forst et al., 1997) (see Fig. BXII.γ.213 in Genus *Xenorhabdus*). This conclusion, originally derived from the analysis of only seven strains (Rainey et al., 1995), was verified when the 16S rDNA analysis was extended to a balanced number of data sets from *Photorhabdus* and *Xenorhabdus* in comparison to other genera and families (Suzuki et al., 1996; Szállás et al., 1997; Fischer-Le Saux et al., 1999). *Photorhabdus*, *Xenorhabdus*, *Proteus*, and *Arsenophonus* can be considered sister genera because they do not branch to a common ancestor with any other group of the family *Enterobacteriaceae* (Liu et al., 1997a).

Poinar isolated a bacterium from a new nematode, *Heterorhabditis bacteriophora* (Poinar, 1975), which was apparently similar to a *Xenorhabdus* sp. but noticeably bioluminescent (Poinar et al., 1977). Poinar et al. proposed to include this luminescent species in the genus as *X. luminescens* (Thomas and Poinar, 1979). The genus *Photorhabdus* was created in 1993, according to the series of arguments described above, to accommodate this species (Boemare et al., 1993). At the present time, it includes three species, *P. luminescens*, *P. temperata*, and *P. asymbiotica*, one of which contains three subspecies, *P. luminescens* subsp. *luminescens*, *P. lumi-*

TABLE BXII.γ.247. Differential characteristics of *Photorhabdus*, *Xenorhabdus*, and *Proteus*[a]

Characteristic	*Xenorhabdus*	*Photorhabdus*	*Proteus*
Bioluminescence	−	+	−
Catalase	−	+	+
Annular hemolysis on sheep blood agar (25°C)	−	d	−
Urease	−	d	+
Indole	−	d	d
H_2S production	−	−	[+]
Nitrate reductase	−	−	+
Acid from D-mannose	+	+	−

[a]Symbols: +, 90–100% of strains are positive; [+], 76–89% are positive; d, 26–75% are positive; −, 0–10% are positive.

nescens subsp. *laumondii*, and *P. luminescens* subsp. *akhurstii* (Fischer-Le Saux et al., 1999). According to the rule 65 (2) of the Code of Nomenclature, generic and subgeneric names that are modern compounds from two or more Latin or Greek words take the gender in the original language of the last component of the compound word. Consequently, *Photorhabdus* genus ending by *rhabdus* (from *rhabdos*, rod in Greek as a feminine word), becomes in modern Latin a feminine word, explaining the feminine names of species and subspecies when they are adjectives (Euzéby and Boemare, 2000). Subspecies names referring to a person take the gender of the person, such as *P. luminescens* subsp. *laumondii* and *P. luminescens* subsp. *akhurstii*.

List of species of the genus Photorhabdus

1. **Photorhabdus luminescens** (Thomas and Poinar 1979) Boemare, Akhurst and Mourant 1993, 254[VP] (*Xenorhabdus luminescens* Thomas and Poinar 1979, 354.)
lu.mi.nes'cens. M.L. pres. part. *luminescens* luminescing, for its luminescence.

Large rods (2 × 0.5 to 6 × 1.4 μm). Occurs as two phase variants. Luminous, with luminescence more than 100-fold greater in phase I. Maximum growth temperature in nutrient broth occurs at 35–39°C. Indole positive. Weak acid produced from fructose, *N*-acetyl-glucosamine, glucose, glycerol, maltose, D-mannose, ribose, and trehalose by most strains. Some strains acidify D-mannitol. Proteinaceous inclusions in the protoplasm of phase I cells; poorly produced in phase II. The natural habitat is in the intestinal lumen of entomopathogenic nematodes of *Heterorhabditis bacteriophora* (Brecon and HP88 groups), and of *Heterorhabditis indica*. Three subspecies have been described.

The mol% G + C of the DNA is: 43–45 (Bd).
Type strain: Hb, ATCC 29999, DSM 3368.
GenBank accession number (16S rRNA): X82248, D78005.

a. **Photorhabdus luminescens** *subsp.* **luminescens** (Thomas and Poinar 1979) Boemare, Akhurst and Mourant 1993, 254[VP] (*Xenorhabdus luminescens* Thomas and Poinar 1979, 354.)

Maximum growth in nutrient broth occurs at 38–39°C. Esculin hydrolysis positive and indole weakly positive. DNase, tryptophan deaminase, and urease negative. Annular hemolysis of sheep and horse blood agars. Does not use DL-lactate as sole source of carbon. D-mannitol used as sole source of carbon and energy. Symbiotically associated with nematodes from the group Brecon of *H. bacteriophora*, the type species of the genus *Heterorhabditis* (Poinar, 1975).

The mol% G + C of the DNA is: 43–45 (Bd).
Type strain: Hb, ATCC 29999, DSM 3368.
GenBank accession number (16S rRNA): X82248, D78005.

b. **Photorhabdus luminescens** *subsp.* **akhurstii** Fischer-Le Saux, Viallard, Brunel, Normand and Boemare 1999, 1654[VP]
ak.hurs'ti.i. M.L. gen. n. *akhurstii* of Akhurst, referring to Dr. R. Akhurst, a major contributor to the bacteriological symbionts of entomopathogenic nematodes.

Maximum growth in nutrient broth occurs at 38–39°C. Esculin hydrolysis positive. Tryptophan deaminase and DNase negative. Urease and indole variable. Annular hemolysis observed on sheep blood agar and, in some strains, on horse blood agar. Utilization of DL-lactate as sole source of carbon variable; weak when positive. D-mannitol used and acidified. DL-glycerate utilization negative. Symbiotically associated with the nematode *H. indica* isolated in warm regions; the first strain (strain D1) was isolated from Australia (Darwin, Northern Territory) by Dr. R. Akhurst.

The mol% G + C of the DNA is: 43–45 (Bd).
Type strain: FRG04, CIP 105564.
GenBank accession number (16S rRNA): AJ007359.

c. **Photorhabdus luminescens** *subsp.* **laumondii** Fischer-Le Saux, Viallard, Brunel, Normand and Boemare 1999, 1654[VP]
lau.mon'di.i. M.L. gen. n. *laumondii* of Laumond, referring to Dr. C. Laumond, a major contributor to the use of entomopathogenic nematode/bacterial complexes for insect pest control.

Maximum growth in nutrient broth occurs at 35–36°C. Esculin hydrolysis, indole, and DNase positive. Tryptophan deaminase variable and urease mostly positive. Total hemolysis on sheep and horse blood agars; the *Photorhabdus* annular reaction is rare. Does not use L-fucose, DL-glycerate, DL-lactate, or D-mannitol. Symbiotically associated with nematodes of the group HP88 of *H. bacteriophora* isolated in South and North America, southern Europe, and Australia, responding to the satellite DNA probe of the nematode strain HP88 provided by the team of Dr. C. Laumond (Grenier et al., 1996).

The mol% G + C of the DNA is: 43–45 (Bd).
Type strain: TT01, CIP 105565.
GenBank accession number (16S rRNA): AJ007404.

2. **Photorhabdus asymbiotica** Fischer-Le Saux, Viallard, Brunel, Normand and Boemare 1999, 1655[VP]
a.sym.bio'ti.ca. Gr. pref. *a* not; M.L. adj. *symbioticus, -a., -um* living together; M.L. fem. adj. *asymbiotica* not symbiotic.

Rods (2 × 0.5 to 3 × 1.0 μm). Maximum growth in nutrient broth occurs at 37–38°C. Yellow or brown pigment. No phase I isolates have been detected, and isolates do not absorb dyes, sometimes weakly produce antibiotics, and are negative for lecithinase on egg yolk agar. Positive for urease, esculin hydrolysis, and for Christensen's citrate, but weakly positive on Simmons' citrate. Tryptophan deaminase negative. Indole and DNase negative. Acid produced from fructose, *N*-acetyl-glucosamine, glucose, maltose, D-mannose, and ribose; weakly produced from glycerol. Proteinaceous inclusions poorly produced. Tween 40 esterase variable. Annular hemolysis on sheep and horse blood agars. Does not use L-fucose, DL-lactate, or D-mannitol. Natural habitat uncertain. All isolates obtained from human clinical specimens.

The mol% G + C of the DNA is: 43–45 (Bd).

Type strain: 3265-86, ATCC 439500.

GenBank accession number (16S rRNA): Z76755.

3. **Photorhabdus temperata** Fischer-Le Saux, Viallard, Brunel, Normand and Boemare 1999, 1655[VP]

tem.pe.ra'ta. L. fem. part. adj. *temperata* moderate, because this species grows at moderate temperature.

Large rods (2 × 0.5 to 6 × 1.4 μm). Occurs as two phase variants. Highly luminous. Maximum growth temperature in nutrient broth occurs at 33–35°C. DNase positive. Most of the strains are indole negative. Esculin hydrolysis and phenylalanine deaminase mostly positive. Urease variable. Acid produced from fructose, *N*-acetyl-glucosamine, glucose, D-mannose, and ribose; weak acid production from glycerol and maltose. Proteinaceous inclusions in protoplasm of phase I cells; poorly produced in phase II. Annular hemolysis often occurs on sheep and horse blood agars. Uses DL-glycerate, and does not use DL-lactate as sole source of carbon. D-mannitol is not used by most strains. The natural habitat is in the intestinal lumen of entomopathogenic nematodes of *Heterorhabditis megidis*, of group NC of *H. bacteriophora*, and of *H. zealandica*.

The mol% G + C of the DNA is: 43–45 (Bd).

Type strain: XlNach, CIP 105563.

GenBank accession number (16S rRNA): AJ007405.

Genus XXVII. **Plesiomonas** *Habs and Schubert 1962, 324*[AL]

J. MICHAEL JANDA

Ple.si.o.mo'nas. Gr. masc. n. *plesios* neighbor; fem. n. *monas* unit, monad; M.L. fem. n. *Plesiomonas* neighbor monad (to *Aeromonas*).

Rod-shaped, straight cells, 0.8–1.0 × 3.0 μm (Janda, 1998). Endospores not produced. Gram negative. **Motile.** Growth on common basal agars with most strains growing on mineral media containing ammonium salts and glucose as sole nitrogen and carbon sources (Schubert, 1984). Chemoorganotrophic with both a respiratory- and fermentative-type metabolism. **Facultatively anaerobic. Acid from the catabolism of D-glucose, without gas.** Anaerogenic fermentation of a limited number of carbohydrates **including *m*-inositol**. **Oxidase and catalase positive. Lysine- and ornithine-decarboxylase and arginine dihydrolase positive. NaCl supplementation not required for growth. Most strains susceptible to 10 μg and 150 μg of the vibriostatic agent O/129 (2,4-diamino-6,7-diisopropylpteridine).** Few extracellular enzymes elaborated (Schubert, 1984). **Starch not hydrolyzed.** 16S rDNA and 16S rRNA analysis indicate plesiomonads belong to the *Gammaproteobacteria*, with maximum homology to members of the *Enterobacteriaceae* (Martinez-Murcia et al., 1992a; Ruimy et al., 1994). Unique genus-specific signature oligonucleotides have not been identified.

The mol% G + C of the DNA is: 51 (Sebald and Véron, 1963).

Type species: **Plesiomonas shigelloides** (Bader 1954) Habs and Schubert 1962, 324 (*Pseudomonas shigelloides* Bader 1954, 455.)

FURTHER DESCRIPTIVE INFORMATION

Contain16S rRNA signature oligonucleotides CUAAUACCG, YCACAYYG (Y = pyrimidine), CUAACUYYG, and UCACACCAUG at positions 170, 315, 510, and 1410 of the *Escherichia coli* numbering system indicative of *Gammaproteobacteria* (Stackebrandt et al., 1988; Martinez-Murcia et al., 1992a). Although previously classified as *Vibrionaceae*, recent phylogenetic data indicates significant evolutionary divergence between *Plesiomonas* and both the *Vibrio/Photobacterium* and *Aeromonas* groups. 5S rRNA, 16S rRNA/rDNA, and 23S rRNA sequence data demonstrate a close phylogenetic relationship between plesiomonads and the *Enterobacteriaceae*, especially the genus *Proteus* (MacDonell et al., 1986; East et al., 1992; Martinez-Murcia et al., 1992a; Ruimy et al., 1994).

P. shigelloides typically appears as short, straight rods without observable curvature. Filamentous bacilli, two to three times the normal cell length, can occur in response to various conditions including exposure to β-lactams (Brenden et al., 1988). Capsules not detected. A heat-labile substance, termed a capsular K or masked antigen by Sakazaki (1984), is produced that inhibits agglutination of cells with homologous O antisera (Farmer et al., 1992). Two types of unsheathed flagella produced. Older cultures express lophotrichous flagellation consisting of a tuft of one to five polar flagella with a wavelength of 3.5–4.0 μm (Ewing et al., 1961; Schubert, 1984). Young cultures (18 h, 25°C) grown on peptone or nutrient based solid media produce peritrichous, curly, flagella with a shorter periodicity of 1.3–1.7 μm (Ewing et al., 1961; Inoue et al., 1991). Up to 68% of young *P. shigelloides* cultures produce lateral flagella when stained with the Flagellar Staining Solution–Shionogi (Inoue and Shimada, 1990; Inoue et al., 1991). Inclusion bodies present in log phase cells consist of polyphosphate granules containing phosphate, potassium, and magnesium (Pastian and Bromel, 1984; Ogawa and Amano, 1987). Laybourn or methylene blue stained inclusions can have bipolar ("safety pin") or central intracellular locations depending on the growth phase (Ogawa and Amano, 1987; Brenden et al., 1988). Intracellular poly-β-hydroxybutyrate granules not formed.

The enterobacterial common antigen (ECA) found exclusively in members of the *Enterobacteriaceae* is present in *Plesiomonas* (Whang et al., 1972; Ramia et al., 1982). ECA appears to be a heteropolymer consisting of *N*-acetylated amino sugars linked to the lipopolysaccharide moiety (Mäkela and Mayer, 1976). Lipid A analysis reveals a common 1,4′-bis-phosphorylated-β-1,6-linked glucosamine backbone with six fatty acid residues either ester-

or amide-linked (Basu et al., 1985). Cellular fatty acid analysis indicates an overall composition similar to other enteric bacteria and *Vibrionaceae* with hexadecanoate ($C_{16:0}$), hexadecenoate ($C_{16:1}$), and octadecanoate ($C_{18:0}$) as major peaks (Lambert et al., 1983; Yamamoto et al., 1991a). Putrescine, cadaverine, and spermidine are the predominant polyamines synthesized (Yamamoto et al., 1991a).

Ultrastructural analysis of *P. shigelloides* reveals a typical cell wall, cytoplasm, and nucleoplasm characteristic of Gram-negative *Bacteria* (Brenden et al., 1988). Electron-dense granules, 50–150 nm in diameter, can be detected as early as 4 h of incubation with maximum size (>500 nm) reached within 12–24 h (Ogawa and Amano, 1987). Electron-transparent vacuoles have also been described (Brenden et al., 1988). Thin section electron micrographs of ruthenium-stained cells demonstrate a string-like acidic mucopolysaccharide material 35 nm thick emanating from the cell surface (Fig. BXII.γ.207). Fimbriae have not been detected.

Plesiomonads produce uniform turbidity in liquid culture without pellicle formation. Autoagglutination rarely observed. Brain heart infusion broth cultures of *P. shigelloides* produce cells with a high surface charge but low hydrophobicity (Abbott et al., 1991). Colonies on nutrient and blood agars are 1.0–2.0 mm in diameter and are smooth, gray, convex, and opaque with an entire edge. Nonhemolytic. Multiple morphovars arising from individual colonies have been reported (Farmer et al., 1992). Cell-associated or diffusible pigments not elaborated; luminescence not observed. Most *Plesiomonas* produce 1.0–2.0 mm flat, colorless colonies on MacConkey, xylose–lysine–desoxycholate, Hektoen enteric, and desoxycholate agars after 24 h growth (Brenden et al., 1988). Delayed lactose fermentation on MacConkey agar by some *P. shigelloides* leads to lactose-positive variants arising upon prolonged incubation, which suggests mixed populations. Salmonella–Shigella, eosin methylene blue, and brilliant green agars are inhibitory to some strains (Brenden et al., 1988).

Growth reported over a wide temperature range (8–45°C); optimal growth occurs at 37–38°C (Schubert, 1984; Miller and Koburger, 1986b). Most plesiomonads multiply in liquid media containing 1–4% NaCl; growth in the presence of 5% NaCl reported to be medium-dependent (Miller and Koburger, 1986b). The pH range for growth has been reported to occur between 4.0–9.0 (Schubert, 1984; Miller and Koburger, 1986b). No growth under extremely acidic (pH 3.0) or alkaline (pH 9.5) conditions.

The genus is biochemically homogeneous. Indole formed. Nitrates reduced. The methyl red test is positive. The Voges–Proskauer test (25°C, 37°C) is negative and acetoin is not produced. No growth in KCN. Citrate, gluconate, malonate, and mucate not utilized; sodium acetate is variable. Phenylalanine deaminase and urease activities absent. The string test (0.5% desoxycholate) is negative. No H_2S produced on triple sugar iron agar slants.

Anaerogenic fermentation of D-glucose, *m*-inositol, maltose, and trehalose. Acid from D-galactose, glycerol, lactose, D-mannose, melibiose, and salicin is variable. No fermentation of adonitol, L-arabinose, cellobiose, dextrin, dulcitol, esculin, α-methyl-D-glucoside, inulin, D-mannitol, melezitose, D-sorbitol, sucrose, L-rhamnose, or D-xylose.

Phosphatase and β-galactosidase (ONPG, O-nitrophenyl-β-D-galactopyranoside) positive. β-D-glucuronidase negative. A number of *P. shigelloides* arylamidases and esterases are detected using semiquantitative micromethods with chromogenic substrates (Manafi and Rotter, 1992). Chitinase elaborated (O' Brien and

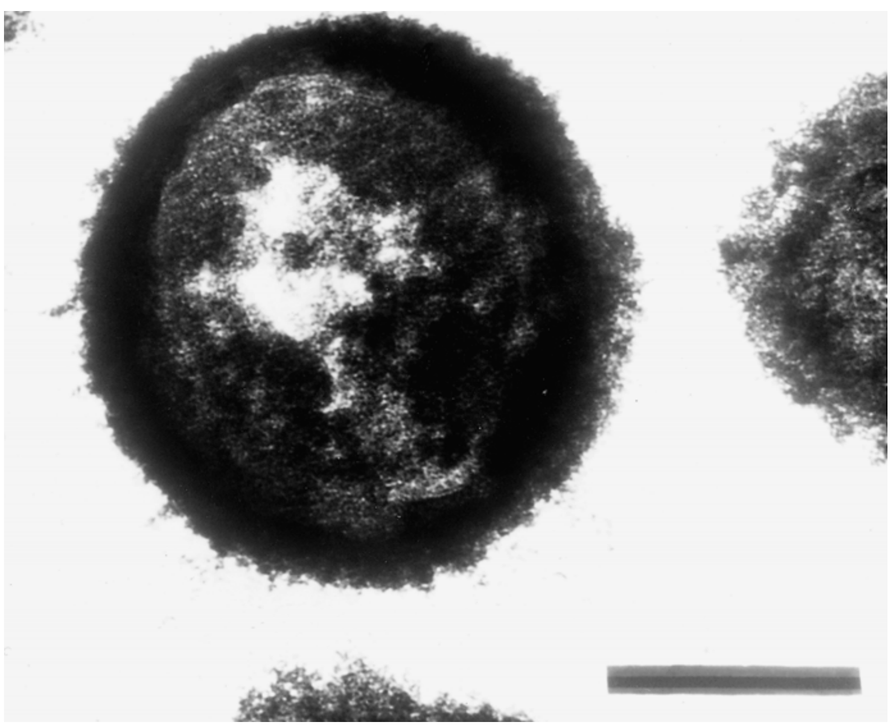

FIGURE BXII.γ.207. Ruthenium-red stained cells of *P. shigelloides* displaying external acidic mucopolysaccharide layer (× 34,000). Bar = 0.5µm. (Reproduced with permission from R.A.Brenden et al., Reviews of Infectious Disease *10:* 303–316, 1988, ©University of Chicago Press.)

Colwell, 1987). Casein, DNA, elastin, fibrinogen, gelatin, polypectate, starch, tyrosine, and Tween 80 are neither degraded nor hydrolyzed.

Formal DNA–DNA hybridization studies on *Plesiomonas* have not been published. Anecdotal information from one epidemiological investigation indicates that all 27 *P. shigelloides* strains constituted a single relatedness group by DNA–DNA hybridization (Holmberg et al., 1986b; Don J. Brenner, personal communication). Between 63 and 100% of *P. shigelloides* strains harbor extrachromosomal elements. Plasmids range in size from 2–8 MDa to very large extrachromosomal elements of 120–312 MDa (Herrington et al., 1987; Ølsvik et al., 1990; Abbott et al., 1991). Plasmid-cured derivatives show loss of expression of β-galactosidase activity (Herrington et al., 1987) and resistance to streptomycin (Marshall et al., 1996). *P. shigelloides* also produces a restriction endonuclease (*Psh* AI) with a novel recognition site of 5′-GACNN/NNGTC (Miyahara et al., 1990). Bacteriocin and phage typing systems have not been described.

An international antigenic scheme recognizes 96 somatic (O) and 48 flagellar (H) antigens of *P. shigelloides* (Aldová and Schubert, 1996). Some serovars show partial or complete identity to *Shigella* somatic antigens. Serovar O17, a common group found in clinical material, reacts with *Shigella* group D antisera (Abbott et al., 1991) and is identical to the O antigen of *S. sonnei* (Sakazaki, 1987). An a, b-a, c type of antigenic relationship also exists between serovar O11 and *S. dysenteriae* 8, serovar O22 and *S. dysenteriae* 7, serovar O23 and *S. boydii* 13, serovar O54 and *S. boydii* 2, and serovar O57 and *S. boydii* 9 (Sakazaki, 1987; Shimada et al., 1994a). Certain plesiomonads share type-specific antigens with *S. flexneri* 6 and common group 1 antigen of *S. dysenteriae* 1 (Albert et al., 1993a). A second unrelated scheme based upon "Schubert" antigens was developed with reference strains from pond water and water insects (Aldová and Schubert, 1996). This scheme is primarily useful in typing environmental isolates; 23 "O" and 5 "H" antigens are recognized.

P. shigelloides is uniformly susceptible *in vitro* to first-, second-, and third-generation cephalosporins, fluoroquinolones, carbapenems, monobactams, and trimethoprim-sulfamethoxazole (Reinhardt and George, 1985; Kain and Kelly, 1989; Clark et al., 1990; Clark, 1992). Widespread resistance to ampicillin, amoxicillin, carbenicillin, mezlocillin, piperacillin, and ticarcillin. Variable results described for tetracycline and aminoglycosides. Most strains produce a β-lactamase using the nitrocefin test (Reinhardt and George, 1985; Clark et al., 1990) but are susceptible to antibiotic-β-lactamase-inhibitor combinations.

The gastrointestinal tract is the primary site from which *P. shigelloides* is recovered. While definitive proof establishing *P. shigelloides* as an enteropathogen is lacking, several lines of evidence support a role in gastroenteritis. These include a low carrier rate, case-controlled investigations, well-circumscribed case reports, and outbreaks of diarrheal disease (Brenden et al., 1988). Carriage rates in asymptomatic individuals range from 0–5.5% with most reported values <0.1% (Arai et al., 1980; Holmberg and Farmer, 1984; Bozsó et al., 1986). Case-controlled investigations have generally found 3- to 20-fold higher isolation rates of plesiomonads from symptomatic patients versus controls (Pitarangsi et al., 1982; Bozsó et al., 1986; Lim et al., 1987). Isolation rates of *P. shigelloides* as high as 22% have been reported from children with bloody diarrhea (Taylor et al., 1986b). Sporadic cases of gastroenteritis have documented high numbers of plesiomonads (3×10^8 CFU/ml) in duodenal biopsies (Penn et al., 1982) and seroconversion to the lipopolysaccharide of infecting strains (van Loon et al., 1989). Two Japanese outbreaks of *P. shigelloides* diarrheal disease caused by serovars O17:H2 and O24:H5 have been associated with contaminated drinking water (Tsukamoto et al., 1978). A third less well-defined outbreak was linked to oyster consumption (Rutala et al., 1982).

P. shigelloides gastroenteritis has been reported around the world. Diarrheal disease can range from a mild enteritis to frank dysentery (Holmberg et al., 1986b; Kain and Kelly, 1989; Rautelin et al., 1995b). Cholera-like illnesses are rare (Sawle et al., 1986). All age groups are affected. Common symptoms include diarrhea with abdominal pain/cramps. Less frequent symptoms include fever, nausea, and vomiting. Risk factors associated with infection include consumption of raw shellfish, foreign travel, and exposure to reptiles and tropical fish (Davis et al., 1978; Van Damme and Vandepitte, 1980; Holmberg et al., 1986b; Tippen et al., 1989).

Extraintestinal disease principally involves septicemia. At least 20 cases have been reported in the literature to date. Most cases of bacteremia involve persons with underlying conditions including neonatality, hematologic dyscrasias, and liver disease (Clark and Janda, 1991; Delforge et al., 1995; Riley et al., 1996). Meningitis accompanying septicemia is primarily a disease of neonates (Billiet et al., 1989). Prolonged membrane rupture prior to delivery predisposes infants to infection (Clark and Janda, 1991). Infrequent extraintestinal complications of *P. shigelloides* infection include biliary disease (Claesson et al., 1984; Körner et al., 1992), pancreatic abscess (Kennedy et al., 1990), pseudoappendicitis (Fischer et al., 1988), arthritis (Gordon et al., 1983), osteomyelitis (Ingram et al., 1987), and ocular infections (Butt et al., 1997a).

Virulence factors are poorly defined (Janda, 1998). Extracellular factors elaborated by select *P. shigelloides* strains include heat-labile and heat-stable enterotoxins (Manorama et al., 1983; Gardner et al., 1987; Matthews et al., 1988) and cytotoxins (Abbott et al., 1991; Albert et al., 1993a). Most strains produce a cell-associated hemolysin that may be responsible for cytotoxic activity (Janda and Abbott, 1993b). Invasion of HeLa and HEp-2 cells has been reported (Binns et al., 1984; Albert et al., 1993a). Sereny (keratoconjunctivitis) test negative. Siderophores not produced (Daskaleros et al., 1991). Human volunteers fed 10^3–10^9 CFU of *P. shigelloides* P012 failed to develop diarrhea (Herrington et al., 1987).

Freshwater environments, including mud and sediment, are the major reservoirs for *P. shigelloides*. A Dutch study (Medema and Schets, 1993) found levels of *P. shigelloides* in surface water samples correlated with fecal pollution (*Escherichia coli*) and the trophic state (chlorophyll *a*, Secchi depth). A subsequent Brazilian investigation did not draw a similar conclusion (de Mondino et al., 1995). A survey of the Suwannee River estuary found most water and sediment samples positive for *P. shigelloides* during three sampling periods (August–February). Flora associated with the ecosystem such as eels, crabs, bream, catfish, crappie, pinfish, clams, and oysters also contained plesiomonads (Miller and Koburger, 1986a). Four of 170 (2.4%) seawater samples were found to contain *P. shigelloides* in one survey (Zakhariev, 1971). Other reported animals found to be colonized with *P. shigelloides* include freshwater fish, tropical fish, dogs, cats, sheep, cows, goats, pigs, monkeys, polecats, turtles, newts, toads, and turkey vultures (Miller and Koburger, 1985; Tippen et al., 1989).

Enrichment and Isolation Procedures

A number of selective media have been designed to recover *Plesiomonas* from environmental samples and contaminated clinical

specimens (e.g., feces). Most of these rely on brilliant green and/or bile salts as inhibitors of competing flora and *m*-inositol, a cyclic polyhydroxyl alcohol, as the differential substrate (von Graevenitz and Bucher, 1983; Farmer et al., 1992). While virtually all *P. shigelloides* are inositol positive, only a limited number of enteric groups (*Enterobacter aerogenes, Klebsiella* spp., *Serratia marcescens*) are capable of fermenting this alcoholic sugar.

Inositol-brilliant green-bile salts agar (IBB)[1] has been found to be the best selective media for the recovery of plesiomonads from both clinical (von Graevenitz and Bucher, 1983) and environmental specimens (Miller and Koburger, 1986a). On IBB, *Plesiomonas* colonies appear whitish to pinkish. IBB was 90% sensitive and 100% specific for the recovery of *Plesiomonas* from artificially seeded stool specimens. Optimum *Plesiomonas*/coliform ratios were obtained using IBB (von Graevenitz and Bucher, 1983). However, thermally injured cells may not be satisfactorily recovered using IBB (Miller and Koburger, 1986a). Plesiomonas differential agar (PDA), a variation of IBB, was found superior to IBB for the recovery of *P. shigelloides* in a Bangladesh study (Huq et al., 1991). PDA incubated at 42°C produced optimal results with large colonies (3 mm). Alkaline peptone water (pH 8.6) has been found to be the best enrichment medium for plesiomonads by most investigators (von Graevenitz and Bucher, 1983; Janda, unpublished results), although some studies have found this broth to be unsatisfactory (Millership and Chattopadhyay, 1984).

Maintenance Procedures

Plesiomonas strains are sturdier than *Vibrio* or *Aeromonas* isolates but more fragile than common members of the *Enterobacteriaceae*. Working cultures can be maintained on motility deeps for several months. Permanent stock cultures can be prepared by lyophilization or by freezing cultures at −70°C using cryoprotective agents such as bovine serum albumin (fraction V).

Procedures for Testing Special Characters

For the demonstration of the properties of *Plesiomonas* strains, the same methods are used as those employed for the characterization of *Aeromonas*, *Vibrio*, and members of the *Enterobacteriaceae* (Schubert, 1984).

Differentiation of the genus *Plesiomonas* from other genera

Although *Plesiomonas* has been transferred to the family *Enterobacteriaceae* based upon phylogenetic relatedness, misidentifications as a *Vibrio* or *Aeromonas* can occur by virtue of the production of cytochrome oxidase. Key differential tests that separate these taxa are listed in Table BXII.γ.248.

Taxonomic Comments

Ferguson and Henderson (1947) initially described *P. shigelloides* as a motile *Enterobacteriaceae* culture ("C27") that possessed the major antigen of *Shigella sonnei* phase I. C2 (now ATCC 14030), however, possessed a number of properties distinct from *S. sonnei* including motility, production of indole, delayed lactose fermentation, and the inability to produce acid from D-mannitol. It was therefore placed in the anaerogenic "Paracolon" group by these authors. Because of polar flagellation, Bader (1954) subsequently placed this C27 in the genus *Pseudomonas*, with the epithet *shigelloides* referring to its *Shigella*-like characteristics (Schubert, 1984). Ewing et al. (1961) proposed that this bacterium be transferred to the genus *Aeromonas* based upon a fermentative metabolism and similarities in morphology, flagella arrangement, and biochemical properties. This recommendation was soon replaced by a proposal to create a new genus for *Aeromonas shigelloides*, *Plesiomonas* (Habs and Schubert, 1962). At least two other proposals have subsequently been made to reassign *P. shigelloides* to either the genus *Fergusonia* or *Vibrio* (Vandepitte et al., 1974).

Current phylogenetic and chemotaxonomic data indicate that plesiomonads are more closely related to the *Enterobacteriaceae* than to any other group (Table BXII.γ.249). These data also include proposed 16S rRNA signature nucleotide differences between the *Enterobacteriaceae* and vibrios (Table BXII.γ.250).

Based on phylogenetic evidence a proposal has been made to reassign *P. shigelloides* to the tribe *Proteeae*, considering the 5S rRNA sequence relatedness to *Proteus mirabilis* and *Proteus vulgaris* (MacDonell and Colwell, 1985). However, this proposal seems untenable as classic defining reactions of the tribe *Proteeae* and the genus *Proteus* are entirely absent in *P. shigelloides* (Table BXII.γ.251).

List of species of the genus Plesiomonas

1. **Plesiomonas shigelloides** (Bader 1954) Habs and Schubert 1962, 324[AL] (*Pseudomonas shigelloides* Bader 1954, 455.)
shi.gel.loi′ des. M.L. fem. n. *Shigella* a generic name; Gr. suffix *eides* similar; M.L. adj. *shigelloides Shigella*-like.

The description of the genus and species are given in Table BXII.γ.252.

Occurs in freshwater and marine environments and inhabitants of those ecosystems including fish, amphibia, and shellfish. Isolated from a variety of animals. Associated with gastroenteritis in healthy adults and children. Occasionally causes systemic infections primarily in persons who are immunocompromised or have underlying illnesses.

The mol% G + C of the DNA is: 51 (Ch).

Type strain: M51, ATCC 14029, CDC 3085-55, DSM 8224, NCIB 9242.

GenBank accession number (16S rRNA): M59159, X74688.

Genus XXVIII. **Pragia** *Aldová, Hausner, Brenner Kocmoud, Schindler, Potužníková, and Petráš 1988a, 187*[VP]

Jiri Schindler, Sr.

Pra′ gi.a. L. fem. n. *Pragia* of Prague, the city in which strains of the genus were identified.

Gram-negative, oxidase-negative, catalase-positive, peritrichously flagellated rods conforming to the definition of the family *Enterobacteriaceae*. Facultatively anaerobic. Colonies approximately 0.5 mm in diameter are formed on nutrient, Endo, and MacConkey agars. Colonies formed on desoxycholate-citrate agar have a black center. Nonhemolytic on sheep blood agar. A *Shigella*-like odor is produced on nutrient agar. A pigsty-like odor is produced on Endo agar overlaid with a sloping surface of agar. Growth at 4°C, **but not at 42°C**. Optimal growth is obtained at temperatures between 22 and 37°C. Fermentative, forms acid without gas from D-glucose and D-galactose. Motile, reduces nitrates to nitrite, **utilizes citrate, produces hydrogen sulfide, and oxidizes gluconate**. The majority of strains is positive for the methyl red test and delayed positive for acid production from

glycerol and *myo*-inositol. Negative reactions in tests for indole production, Voges–Proskauer test, phenylalanine deaminase, lysine and ornithine decarboxylases, arginine dihydrolase, urease, deoxyribonuclease, malonate, ONPG, growth in KCN, and acid production from L-arabinose, cellobiose, dulcitol, lactose, maltose, D-mannitol, D-mannose, melibiose, raffinose, L-rhamnose, D-sorbitol, D-sorbose, starch, sucrose, and trehalose. Additional biochemical reactions are given in Table BXII.γ.193 of the chapter on *Enterobacteriaceae*.

The mol% G + C of the DNA is: 46–47.

Type species: **Pragia fontium** Aldová, Hausner, Brenner Kocmoud, Schindler, Potužníková, and Petráš 1988a, 187.

Further descriptive information

Pragia is a member of the *Gammaproteobacteria*. Pragia DNA is 17% or less related to members of all other genera in *Enterobacteriaceae*. Bacteriocin-like agents called fonticins were observed in five *P. fontium* strains. They were active against other *P. fontium* strains as well as against *Budvicia aquatica*, but were not active against *Escherichia coli* or *Shigella sonnei*. Similar bacteriocin-like agents, budvicins, with the same specificity and properties have been isolated from *Budvicia aquatica*. Fonticins have very narrow inhibition zones on indicator strains, are heat sensitive (inactivated at temperatures between 42 and 55°C) and are resistant to trypsin (Šmarda, 1987). They are of corpuscular nature and resemble contracted tails of T4 bacteriophage (Šmarda, 1987). Isolated from fresh water springs or fountains in the South Bohemia region of the Czech Republic (Aldová et al., 1983, 1988b). One human isolate not associated with disease. There is no evidence of pathogenicity for humans or animals.

Differentiation of the genus *Pragia* from other genera

Pragia is easily distinguishable from leminorellae, *B. aquatica*, *C. freundii*, and salmonellae based on whole cell protein analysis (Aldová et al., 1988a; Schindler et al., 1992). Biochemical tests useful in differentiating *Budvicia* from other H_2S-positive genera in *Enterobacteriaceae* are shown in Table BXII.γ.253.

Genus XXIX. **Proteus** *Hauser 1885, 12[AL]*

John L. Penner

Pro' te.us. Gr. n. *Proteus* an ocean god able to change himself into different shapes.

Straight rods, 0.4–0.8 × 1.0–3.0 µm. Gram negative. **Motile** by peritrichous flagella. **Most strains swarm with periodic cycles of migration producing concentric zones, or spread in a uniform film, over moist surfaces solidified with agar or gelatin.** The organisms in this genus conform to the definition of the family *Enterobacteriaceae*. **They are facultatively anaerobic, chemoorganotrophic, having both a respiratory and a fermentative type of metabolism.** Optimal growth temperature is 37°C. **Oxidase negative; catalase positive. Methyl red positive; species vary in indole production, Voges–Proskauer, and Simmons citrate tests. They oxidatively deaminate phenylalanine and tryptophan. Urea is hydrolyzed. Lysine decarboxylase negative and arginine dihydrolase negative; only *Proteus mirabilis* decarboxylates ornithine. All but *Proteus myxofaciens* decompose tyrosine to produce a clearing on**

agar media in which the insoluble amino acid is incorporated. Grow on KCN. H_2S is usually produced. Malonate is not utilized. D-glucose and a few other carbohydrates are catabolized with production of acid and usually gas. Does not produce acid from inositol or from straight chain tetra-, penta-, or hexahydroxy— alcohols, but generally produces acid from glycerol. One or more species ferment maltose, sucrose, trehalose, and D-xylose. Human pathogens, causing urinary tract infections; also are secondary invaders, causing septic lesions at other sites of the body. Occurs in the intestines of humans and a wide variety of animals; also occurs in manure, soil, and polluted waters. *P. myxofaciens* has been isolated only from gypsy moth larvae. Based on 16S rDNA sequence analysis, *Proteus* belongs to the family *Enterobacteriaceae* within the *Proteobacteria* (Woese et al., 1985; Niebel et al., 1987; Stackebrandt et al., 1988).

The mol% G + C of the DNA is: 38–41 (Falkow et al., 1962).

Type species: **Proteus vulgaris** Hauser 1885, 12 emend. Brenner, Hickman-Brenner, Holmes, Hawkey, Penner, Grimont and O'Hara 1995, 870.

Further descriptive information

Comparative analysis of 16S ribosomal RNA sequences (the oligonucleotide cataloging method) showed that *P. mirabilis* belongs to the *Gammaproteobacteria*, which includes the family *Enterobacteriaceae* (Woese et al., 1985; Stackebrandt et al., 1988). DNA relatedness studies have shown that members of the genus *Proteus* are only distantly related to the other species in the family *Enterobacteriaceae* and from an evolutionary standpoint they are therefore at the periphery of this family (Brenner et al., 1978). *P. mirabilis* strains are a highly related group. They are 55% related to *P. vulgaris* and to *P. penneri* strains. *P. penneri* consists of a highly related group of indole-negative strains that ferment salicin and hydrolyze esculin. They were classified as *P. vulgaris* biogroup 1 (Brenner et al., 1978) before they were recognized as a new species (Hickman et al., 1982c). At present, *P. vulgaris* consists of two biogroups. *P. vulgaris* biogroup 2 consists of strains that are indole positive, that ferment salicin and hydrolyze esculin. Strains of this biogroup conform to the description of the genus and include the vast majority of the *P. vulgaris* strains isolated from clinical sources. Computerized analysis of electrophoretic protein patterns and DNA relatedness tests showed that *P. vulgaris* biogroup 3 strains (indole positive, salicin negative, and esculin negative) are a heterogeneous group that includes four genomospecies, one of which includes the type strain (Costas et al., 1993; Brenner et al., 1995). Future studies will likely lead to the identification of new species within this biogroup.

On media solidified with gelatin or agar, the bacteria migrate from the point of inoculation to spread over the surface of the medium. The phenomenon, known as swarming, is attributed to the dimorphic nature of the bacteria. The short mononucleoid, peritrichously flagellated rods that occur singly in liquid media, referred to as swimmers, differentiate when transferred to solid media to produce long, nonseptate, multinucleoid swarmers with large increases in the number of flagella (Belas, 1992). Glutamine has been identified as the chemoattractant that signals the surface-induced differentiation (Allison et al., 1993). Differentiation into swarmer cells is associated with marked increases in synthesis of lipopolysaccharide with long O-polymers and a higher fluidity of the outer membrane (Sidorczyk and Zych, 1986). The production also of extracellular slime forming a thin cocoon covering swarms of cells (VanderMolen and Williams, 1977) or capsular polysaccharide containing galacturonic acid and *N*-acetylgalactosamine facilitates migration of swarmer cells (Stahl et al., 1983; Gygi et al., 1995). Swarmer cells are the virulent forms of *Proteus* and during differentiation a coordinated increase occurs in the synthesis of urease, hemolysins, and proteases (Jin and Murray, 1987; Allison et al., 1992, 1994).

Three phases have been recognized in the process of swarming. In the first phase, differentiation of swimmer cells into swarmer cells takes place. In the second phase, groups of swarmer cells migrate from the point of inoculation and continue to migrate until either a change in direction occurs or the number of swarmers is reduced by a loss of some along the way. In the third phase, migration ceases, which results in consolidation. At this point, the swarmer cells form septa to become short cells that multiply for a period of time before producing another generation of swarmer cells (Williams and Schwarzhoff, 1978; Rózalski et al., 1997). Cyclic repetitions of the phases leads to concentric rings surrounding the site of inoculation. Some strains (or variants) produce a uniform film (referred to as spreading) without periodic cycles (C variant of Belyavin, 1951; Z variant of Coetzee and Sacks, 1960). Some strains neither spread nor swarm and merely form distinct colonies.

The swarming of *Proteus* makes it difficult to isolate bacteria of other species from pathological specimens plated on agar media and to prevent swarming; inhibitors such as bile salts and detergents are incorporated in the media (Kopp et al., 1966). The compound *p*-nitrophenyl glycerol, at concentrations of 0.1–0.3 mM, inhibits swarming without affecting flagellation or motility, and because of its low toxicity to *Proteus* and other bacteria, its use has been advocated (Williams, 1973). With continued incubation, however, the *Proteus* strains eventually swarm in the presence of this compound and thus isolations of *Campylobacter* species and other bacteria that require longer periods of incubation require other measures such as the incorporation of antibiotics in the isolation media (Firehammer, 1987). The incorporation of charcoal in the medium has been reported to suppress swarming without interfering with the growth of other bacterial species (Alwen and Smith, 1967). Other methods of preventing swarming include reduction of the salt concentration of the media and increasing the concentration of agar to 4% (New Zealand agar) or 7% (Japanese agar).

In the Dienes test, swarms of two strains that do not penetrate into each other but form a sharp line between them indicate that the strains are different but strains that produce swarms that merge into each other without a line of demarcation are interpreted to be the same (Dienes, 1946). This test has been used in epidemiological investigations of *Proteus* infections, mostly of *P. mirabilis*, to determine identity and nonidentity of clinical isolates (Story, 1954; Skirrow, 1969). However, strains of different biovars have been found to swarm into each other (Kippax, 1957), and, in some cases, results obtained with the test fail to correlate with bacteriophage typing results (Hickman and Farmer, 1976). The production of the demarcation line is apparently unrelated to the flagellar (H) antigens (Sourek, 1968; Skirrow, 1969) but appears to be dependent on both the bacteriocins produced by the swarming strains and the bacteriocins to which they are susceptible (Senior, 1977a). The Dienes test is useful in combination with other procedures for epidemiological typing and when its limitations are recognized.

A well-known distinguishing feature of the genus is the production of urease. It is an important taxonomic criterion that differentiates the genus from most other species of *Enterobacteriaceae* except for the genera *Morganella* and *Providencia*, some

species of which also produce the enzyme. The enzyme is constitutive in most strains of *P. mirabilis* and inducible in *Proteus vulgaris*, *Proteus penneri*, and some *P. mirabilis* strains (Mobley et al., 1987; 1995; McLean et al., 1988; Mobley and Hausinger, 1989). The enzyme is a 212–280 kDa protein consisting of three subunits (Jones and Mobley, 1989; Mobley and Hausinger, 1989) and is known to have an important role in the development of human urinary tract infections (Mobley, 1996).

An important distinguishing feature of *Proteus*, *Providencia*, and *Morganella* is their ability to oxidatively deaminate a variety of amino acids, producing keto acids and ammonia (Bernheim et al., 1935; Stumpf and Green, 1944; Singer and Volcani, 1955). The carboxylic acids bind iron and have siderophore activity (Evanylo et al., 1984; Drechsel et al., 1993). Addition of ferric chloride solution to keto acids in aqueous solution produces different colors dependent upon the amino acid from which the keto acid was produced (Singer and Volcani, 1955), and the same colors are produced when ferric chloride solution is added to bacteria grown on nutrient media supplemented with the amino acids. This is the basis of the diagnostic test used in the clinical laboratory to distinguish these three genera from other *Enterobacteriaceae*. Tests for phenylalanine deaminase and tryptophan deaminase are widely used (Henriksen, 1950; Thibault and Le Minor, 1957). The gene encoding an amino acid deaminase (*aad*) in *P. mirabilis* has been identified (Massad et al., 1995). The probe for the *aad* gene does not hybridize with DNA from *Providencia* and *Morganella* strains, suggesting that the deaminases of these three genera are unrelated. As with ureases, an end product of the deaminases is ammonia, which is now known to have an important role in pathogenesis by elevating pH, but the contributions of the deaminases in the pathogenic process have yet to be determined (Rózalski et al., 1997).

The production of amines by *Proteus* species and *Morganella morganii* when grown in nutrient broth is a distinguishing biochemical property of the two genera (Proom and Woiwod, 1951). The inability of *Providencia rettgeri*, classified during that period as *Proteus rettgeri*, to produce amines under these conditions was cited as an important criterion in their proposal for removing this species from the genus *Proteus*. Simplified tests to detect amines for differentiation of these genera from other *Enterobacteriaceae* in the clinical laboratory have not been developed. However, the amines continue to be of interest, particularly with the finding that a carcinogenic nitrosamine (*N*-nitrosodimethylamine) is produced in urine by *P. mirabilis* during the course of a urinary tract infection (Brooks et al., 1972).

The antigens of the genus *Proteus* that are used for differentiating the serovars are the lipopolysaccharide (O) antigens, the flagellar (H) antigens, and the capsular (K or C) antigens. The O antigenic scheme of Kauffmann and Perch for *P. vulgaris* and *P. mirabilis* (Kauffmann, 1966) lists 49 serovars. Tube agglutination tests and cell suspensions boiled for 1 h were used to determine the O specificities. Additional serovars have been identified that are not included in the scheme of Kauffmann and Perch (Larsson and Olling, 1977; Penner and Hennessy, 1980).

Seventeen serovars of the Kauffmann and Perch scheme were found to include only *P. vulgaris* strains, 27 included only *P. mirabilis* strains, and five included strains of both species. Since isolates generally agglutinate in antisera against the same species, separation of the serovars to provide individual schemes for each species facilitated routine serotyping (Penner and Hennessy, 1980). In the system developed by Penner and Hennessy for serotyping *P. vulgaris* and *P. mirabilis*, the passive (indirect) hemagglutination technique was employed to determine the specificities of soluble heat extracted antigens. Their system included 22 *P. vulgaris* and 32 *P. mirabilis* strains from the Kauffmann and Perch scheme, five new serovars of *P. vulgaris*, and six new serovars of *P. mirabilis*. However, from the large numbers of untypeable smooth strains isolated in epidemiological studies, it is clear that a substantial number of serovars remain undefined (Larsson and Olling, 1977; Larsson, 1980, 1984; Penner and Hennessy, 1980). Reports differ on the distributions of serotypes of *P. mirabilis*, but among those listed the most frequently occurring are isolates of O serotypes 3, 6, 10, 27, and 28 (Lányi, 1956; de Louvois, 1969; Larsson and Olling, 1977; Penner and Hennessy, 1980; Rózalski et al., 1997). In these earlier studies the strains of *P. vulgaris* were not differentiated into biogroups and thus the collections included a few biogroup 1 strains that would now be classified as *P. penneri* (Hickman et al., 1982c). A system for serotyping *P. penneri* has not been developed. However, one serotypically homogeneous group of strains collected from three countries has been identified and designated group O61 (Sidorczyk et al., 1996). The molecular structures of the lipopolysaccharides of at least 10 different strains of *P. penneri* have been determined (Zych et al., 1997). Examination of the variety of structures suggests the possibility that more serotypes will be defined in the future.

Much research has recently focused on the structures of the lipopolysaccharide (LPS) of *P. vulgaris*, *P. mirabilis*, and *P. penneri*, and progress in this area has been the subject of a major review (Rózalski et al., 1997). The structure of lipid A is comparable to the lipid A of *Escherichia coli* and salmonellae but differs in its fatty acid composition and in the presence of a 4-deoxy-arabinosyl residue that substitutes the phosphate residue of glucosamine (Sidorczyk et al., 1983). The biological activity of *Proteus* lipid A is comparable to that of *E. coli* and salmonellae (Sidorczyk et al., 1978). The core oligosaccharides of *P. vulgaris* and *P. mirabilis* consist of Kdo (3-deoxy-D-*manno*-octulosonic acid), heptoses, and hexoses, as in *E. coli* and salmonellae, but differ in that they have terminal or chain-linked galacturonic acids that contribute significantly to the immunospecificity of the oligosaccharide (Kotelko, 1986; Sidorczyk et al., 1987). The O-polysaccharide polymers consist of repeating units composed of hexoses, hexosamines, 6-deoxy sugars, uronic acids with amino acids attached to their carboxyl groups, and other noncarbohydrate acidic components (Sidorczyk et al., 1975; Kotelko, 1986; Sidorczyk et al., 1995).

P. vulgaris strains OX19 and OX2 and *P. mirabilis* strain OXK are the test strains for O antigens 1, 2, and 3, respectively, in the antigenic scheme of Kauffmann and Perch (Kauffmann, 1966). Antibodies in sera from patients with rickettsial infections agglutinate either one or two of these strains. This reaction is the basis of the Weil-Felix test, which is a presumptive test for rickettsial infections. Sera from patients with endemic or epidemic typhus agglutinate the OX19 strain, patients infected with the spotted fever group of rickettsiae agglutinate both OX19 and OX2 strains, and patients with scrub typhus agglutinate the OXK strain. The reactions have been suspected to be due to LPS and the finding that sera from patients with spotted fever react with LPS from both the rickettsial strain and the *P. vulgaris* OX2 strain indicates this to be the case (Amano et al., 1993). Since *Proteus* infections may also stimulate antibody production and *P. mirabilis* strains with the O3 antigen are among the most frequently isolated, positive Weil-Felix tests should be interpreted with caution. Furthermore, the heterophile antigens to which the cross-reactions in the Weil-Felix test are attributed also occur in *Legionella*

bozemanii and *Legionella micdadei*, indicating that these antigenic specificities are more widely distributed than originally believed (Sompolinsky et al., 1986; Westfall et al., 1986).

Analysis of the flagellar (H) antigens of *P. vulgaris* and *P. mirabilis* was carried out by Perch (1948). A total of 19 were identified and included in the Kauffmann and Perch antigenic scheme (Kauffmann, 1966). Cross-reactions among the H antigens are numerous and complex. Five antigenic factors were identified in the H 1 complex and other H antigens showed even greater complexity. The use of H antigens for routine serotyping of *P. vulgaris* and *P. mirabilis* strains has not been adopted and has been limited essentially to the initial studies of Kauffmann and Perch (Perch, 1948). The flagellar antigens of *P. penneri* have not been investigated.

Capsular antigens, unlike the K antigens of other *Enterobacteriaceae*, were reported to be present in the genus *Proteus* (Namioka and Sakazaki, 1959). These antigens, designated C antigens to distinguish them from the *E. coli* L and B antigens, inhibit O agglutination, retain antibody binding capacity after 1 h at 100°C, and have antigenic specificities restricted to certain O groups. The authors suggested that numerous serological types of C antigens occur in the genus *Proteus*, but a system for identifying them has not been developed. Research has focused on the role of capsules in facilitating swarming (Stahl et al., 1983), and a polysaccharide that evidently has this effect has been identified and chemically characterized (Gygi et al., 1995). Investigations are also under way to examine the role of polysaccharide capsules or glycocalyces in the formation of biofilms during infections of the urinary tract. It has been hypothesized that the biofilm is a major virulence factor because it enhances bacterial adhesion, surrounds the bacteria to protect them from the immune response and from exposure to antibiotics, and provides a microenvironment in the kidney and bladder that is conducive to stone formation (Nickel et al., 1985; McLean et al., 1988; Clapham et al., 1990).

Since the last edition of the *Manual*, numerous investigations of the surface structures of *P. vulgaris*, *P. mirabilis*, and *P. penneri* have resulted in clarification of the nature of the well-known hemagglutinins and fimbriae and in the discovery of several new types of fimbriae. A greater understanding of the mechanisms of pathogenesis has been gained. The MR/P (mannose resistant *Proteus*-like) fimbriae, also known as type IV fimbriae, have been the most extensively studied. These are highly immunogenic proteins 7 nm in diameter. The MR/P fimbriae have been isolated and purified and the genes involved in their determination have been identified (Sareneva et al., 1990; Bahrani et al., 1991; Bahrani and Mobley, 1993, 1994). Evidence obtained in experiments using the mouse model indicates that these fimbriae are associated with colonization of the upper regions of the urinary tract (Bahrani et al., 1994).

The MR/K (mannose resistant, *Klebsiella*-like) type 3 hemagglutinins are thin (diameter of 4–5 nm) and hemagglutinate tanned erythrocytes. Two antigenic types have been found but neither type is antigenically related to *Klebsiella* fimbriae (Old and Adegbola, 1982). MR/K hemagglutinins are more characteristic of *P. penneri* than of *P. mirabilis* (Yakubu et al., 1989). *Proteus* strains with MR/K hemagglutinins have a high affinity for the materials of which catheters are made, and this feature has been cited as a factor in prolonged chronic urinary tract infections of catheterized patients (Mobley et al., 1988; Yakubu et al., 1989; Roberts et al., 1990).

Of the newly discovered fimbriae, one type designated PMF for *P. mirabilis* fimbriae, has been suggested to be important in the colonization of the bladder, but not the kidney (Bahrani et al., 1993; Massad et al., 1994b). Another type, referred to as ambient temperature fimbriae (ATF) of *P. mirabilis*, is optimally produced at 23°C and apparently does not have a role in pathogenesis (Massad et al., 1994a). A third type, also expressed by *P. mirabilis*, was referred to as nonagglutinating fimbriae (NAF) (Tolson et al., 1995). It does not have the hemagglutinating properties of MR/P or MR/K fimbriae, but adheres to uroepithelial cells, indicating possible importance as a virulence factor in establishing urinary tract infections.

The ability of *Proteus* species to produce cytotoxic hemolysins has been known since 1919 (Wenner and Rettger, 1919), but definitive studies had to await the development of molecular biological technologies. With the aid of new techniques, it has been established that *Proteus* species produce two distinct hemolysins (Welch, 1987). The HlyA hemolysin is genetically related to the α-hemolysin of *E. coli*, has a molecular size of 110 kDa, and is a Ca^{2+}-dependent, pore-forming cytotoxin (Koronakis et al., 1987, Welch, 1991). The HpmA hemolysin (166 kDa) is related to the ShlA hemolysin of *Serratia marcescens* and is calcium independent (Uphoff and Welch, 1990). A protein, HpmB (63 kDa), which is closely related to the ShlB protein of *S. marcescens* is responsible for the transport and activation of the HpmA protein (Swihart and Welch, 1990b; Uphoff and Welch, 1990). Nearly all the *P. vulgaris* and *P. mirabilis* strains produce the HpmA hemolysin, but only a few *P. vulgaris* produce the HlyA hemolysin (Swihart and Welch, 1990a). Most strains of *P. penneri* produce the HpmA hemolysin and most also produce the HlyA hemolysin (Rózalski and Kotelko, 1987; Lukomski et al., 1990; Senior, 1993). Expression of hemolysins is associated with increased cytotoxicity, cell invasiveness, and a lower LD_{50} in mice, but is not associated with increased kidney colonization or histopathological changes in murine urinary tract infections (Peerbooms et al., 1983, 1984, 1985; Mobley and Chippendale, 1990).

Proteus spp. are among the few Gram-negative species capable of producing proteolytic enzymes that degrade immunoglobulins. Strains of *P. vulgaris*, *P. mirabilis*, and *P. penneri* have been shown to produce immunoglobulin A (IgA) proteases (Senior et al., 1988; Wassif et al., 1995). Analysis of the proteolytic activity of one *P. mirabilis* strain isolated from a patient with urinary tract infection showed that it has a much wider range of activity than the usual IgA proteases. Both serum and secretory IgA1 and IgA2, both the free and IgA-bound secretory component, and IgG are susceptible targets of this enzyme but its role as a virulence factor in urinary tract infections remains uncertain (Loomes et al., 1990). A polypeptide with protease activity that is secreted by uropathogenic *P. mirabilis* has been implicated as a virulence factor in enhancing the ability of the organisms to infect the urinary tract (Zhao et al., 1999).

The antibiotic susceptibility of *P. myxofaciens* is not known but a feature common to the other three *Proteus* species is an intrinsic resistance to bacitracin and the polymyxins (Potee et al., 1954; Von Graevenitz and Nourbakhsh, 1972; Shimizu et al., 1977). Susceptibility to colistin (colymycin) is rare among *Proteus* species, and if a strain is susceptible to this antibiotic, it is most likely not to be a *Proteus* (Li and Miller, 1970). These cyclic polycationic antibiotics are believed to bind to the charged Kdo-lipid A region of the LPS to cause membrane disruption. Substitution of the phosphate ester bonds of the lipid A with L-arabinoso-4-amine in *Salmonella typhimurium* leads to resistance of the bacteria to polymyxin (Vaara et al., 1981). *Proteus* strains have lipid A that

contains L-arabinoso-4-amine naturally, and this has been suggested as a contributing factor for their natural resistance to these antibiotics (Sidorczyk et al., 1987; Rózalski et al., 1997).

P. mirabilis is the species most frequently isolated from human infections and is generally also the most susceptible to antibiotics, but some very resistant isolates have been reported (Penner et al., 1982). Increasing resistance, particularly to tetracyclines, has been noted since the 1950s (Potee et al., 1954; Chiu and Hoeprich, 1961). The majority of the strains are susceptible to chloramphenicol, but many carry an inducible chloramphenicol acetylase gene (Charles et al., 1985) that could lead to failure in the treatment of brain abscesses (Hawkey, 1997). The occurrence of both nitrofurantoin-sensitive and nitrofurantoin-resistant strains in clinical specimens has been reported.

P. mirabilis is the most susceptible of the three species to the β-lactam group of antibiotics, although resistant strains occur and the necessity of performing antibiotic susceptibility tests is stressed (Barry and Hoeprich, 1973; Shafi and Datta, 1975). *P. mirabilis*, unlike the other two species, does not appear to carry a chromosomal cephalosporinase or an AmpC type penicillinase, and thus many infections can be treated with either cephalosporins or ampicillin (Livermore, 1995). Only rarely is imipenem-resistant *P. mirabilis* isolated, and it has been suggested to be due to altered penicillin-binding proteins (Neuwirth et al., 1995).

Most strains of *P. mirabilis* are susceptible to aminoglycosides, but some strains may acquire resistance factors (R factors) that cause resistance to gentamicin and kanamycin. Amikacin is effective against *P. mirabilis* strains but some have been reported to be resistant to this antibiotic as well as to gentamicin (Briedis and Robson, 1976; Drasar et al., 1976). Resistant *P. mirabilis* can be anticipated to be more frequently encountered in the future, especially in hospital outbreaks, as increased usage has been shown in the past to lead to increased resistance.

Antibiotics generally used to treat infections caused by *P. mirabilis* are trimethoprim or one of the fluoroquinolones such as ciprofloxacin. However, susceptibility tests should be performed for each isolate (Hawkey, 1997).

P. vulgaris is separable into two biogroups, but most of the data on antibiotic susceptibility do not distinguish strains on this basis, and results of antibiotic susceptibility studies in earlier periods did not distinguish between *P. vulgaris* and *P. penneri*. Assessments of the susceptibilities of *P. vulgaris* have been made based on mixtures of strains. However, it is now clear that *P. vulgaris* strains are more resistant than *P. mirabilis* strains. The high levels of *P. vulgaris* resistance to penicillins and cephalosporins is a feature distinguishing it from *P. mirabilis*. Carbenicillin is the only penicillin that has been shown to have significant activity against *P. vulgaris* strains. Most strains, however, are susceptible to aminoglycosides. A small percentage are resistant to gentamicin and kanamycin, but, in most cases, are susceptible to amikacin. Both chloramphenicol-resistant and chloramphenicol-susceptible *P. vulgaris* strains have been reported to be present in clinical specimens, but it is not known what proportion of these would now be classified as *P. penneri*, which are characteristically resistant to this antibiotic (Hickman et al., 1982c).

The high levels of resistance of *P. penneri* strains to chloramphenicol is a definitive criterion in the description of the species (Hickman et al., 1982c). Although increasing numbers of laboratories are identifying *P. penneri* strains, the numbers reported in susceptibility studies are relatively small for a general assessment of the susceptibility of the species. Reports from several laboratories, however, confirm the resistance to chloramphenicol as a species characteristic (Hickman et al., 1982c; Hawkey et al., 1983; Fuksa et al., 1984; Piccolomini et al., 1987). It also appears that the species is more resistant to penicillins than is *P. vulgaris*. In a study of 45 isolates, it was found that ceftizoxime, ceftazidime, moxalactam, and cefoxitin would be effective for treatment of *P. penneri* infections (Fuksa et al., 1984). In another study of 39 isolates, imipenem was found to be the most effective antibiotic against isolates of this species (Piccolomini et al., 1987). Isolates were also found to be susceptible to four aminoglycosides (gentamicin, tobramycin, netilmicin, and amikacin), and their use was recommended for treatment of systemic infections (Fuksa et al., 1984). Isolates of the three species are susceptible to the quinolones, particularly to ciprofloxacin and norfloxacin, but a small number of *P. penneri* isolates show higher levels of resistance (Hawkey and Hawkey, 1984).

P. vulgaris, *P. mirabilis*, and *P. penneri* are important human pathogens causing primary and secondary infections. Of the three species, *P. mirabilis* is most frequently isolated from clinical specimens and is one of the most important pathogens of the urinary tract. Underlying conditions such as diabetes or structural abnormalities of the urinary tract are associated with infections acquired outside the hospital (Grossberg et al., 1962; Wallace and Petersdorf, 1971). Hospital-acquired infections commonly occur in patients with predisposing conditions such as catheterization, urological instrumentation, or surgery of the urinary tract. Infectious strains are transmitted from the intestinal flora of the patient or contracted through transmission from other patients or from a common reservoir (Dutton and Ralston, 1957; Kippax, 1957; Chow et al., 1979). *Proteus* urinary tract infections may give rise to bacteremias that are difficult to treat and often fatal. *Proteus* bacteria may cause infections at other sites of the body if favorable conditions exist. They may cause infections of wounds, burns, and respiratory tracts and have been isolated from the eyes, ears, and the throat. *Proteus* strains may also infect the neonatal umbilical stump, and fatal bacteremias and meningitis may result (Becker, 1962; Librach, 1968; Shortland-Webb, 1968; Burke et al., 1971). *P. mirabilis* has also been isolated from both children and adults with osteomyelitis (Levy and Ingall, 1967; Meyers et al., 1973).

Proteus species have been implicated as causative agents of enteritis and were isolated from 46.2% of infants with diarrhea (Lányi, 1956). However, in light of the fact that approximately one-quarter of the population are intestinal carriers of *Proteus*, it is difficult to assess this finding as convincing evidence of a role for strains of this genus in the etiology of human enteritis. Furthermore, species of the genus *Campylobacter* that are now known to be major causes of human diarrhea were not recognized at the time of the earlier studies.

Recent research on the modification of peptidoglycan (murein) by bacterial enzymes of Gram-positive and Gram-negative bacteria suggest possible involvement of *P. vulgaris* and *P. mirabilis* in the development of arthritic syndromes. It has been demonstrated that one strain of *P. vulgaris* and 17 strains of *P. mirabilis* possess acetyltransferase activity for converting the muramyl residue of peptidoglycan to the 2,6-diacetylmuramyl derivative (Fleck et al., 1971; Gmeiner and Kroll, 1981; Dupont and Clarke, 1991; Clarke and Dupont, 1992). This has the effect of creating resistance of the peptidoglycan to the hydrolytic enzymes in phagocytic cells and serum, resulting in the persistence and circulation in the host of high molecular weight peptidoglycan fragments, which have been implicated in animal models as the inciting agents of rheumatoid arthritis (Chedid et al., 1978; Cro-

martie, 1981; Clarke and Dupont, 1992). It is also noteworthy that antibodies against *Proteus* species have been detected in patients with rheumatoid arthritis (Ebringer et al., 1985). The possibility that organisms of the genus *Proteus* could be involved in the development of rheumatoid arthritis is an interesting concept, but more research is required (Clarke and Dupont, 1992).

Epidemiological typing is performed at present only for *P. vulgaris* and *P. mirabilis*. For reference work, O-serotyping is the method widely accepted as the standard but it is carried out only in a few laboratories that have the large set of typing antisera (Perch, 1948; Kauffmann, 1966; Penner and Hennessy, 1980; Larsson, 1984; Hawkey et al., 1986b). The antisera are not commercially available, and other systems for typing have been introduced and tested with the objective of enabling clinical laboratories to conduct epidemiological studies without the high costs associated with O-serotyping. Among these alternative methods is the Dienes test (described above), which can be readily performed but lacks specificity (Kippax, 1957; Hickman and Farmer, 1976). The incompatibility of two swarms that produce a line of demarcation between them is believed to be due to both the production of and susceptibility to bacteriocins (Senior, 1977a). Typing based on sensitivity to bacteriocins (proticins) has been advocated since 1965 (Cradock-Watson, 1965), and several systems have been developed (Al-Jumaili, 1975; Senior, 1977b; Kusek and Herman, 1980). In a study using the proticine production and proticine sensitivity method, O serotyping, and the Dienes test, a highly discriminating system for identifying *P. mirabilis* and *P. vulgaris* strains, was achieved (Senior and Larsson, 1983). The results also showed that the Dienes test was useful in determining the presence of a common type among a small number of isolates, but not when applied to a large number of isolates for which testing of many combinations is required. In such cases, proticine typing or O serotyping are more appropriate. The greatest discrimination is provided by using both proticine and O serotyping.

Lytic bacteriophage may also be used to differentiate strains of *P. vulgaris* and *P. mirabilis*; several groups of investigators have described typing schemes (Vieu and Capponi, 1965; France and Markham, 1968; Izdebska-Szymona et al., 1971; Schmidt and Jeffries, 1974; Hickman and Farmer, 1976; Bergan, 1978).

A high level of discrimination among *P. mirabilis* strains may also be achieved by testing the strains for growth inhibition in a selected group of chemicals that does not include antibiotics (Kashbur et al., 1974). This method of typing, referred to as resistotyping, was found to compare favorably with serotyping, phage typing, proticine typing, and the Dienes test.

Traditional methods of typing are now being supplanted by new techniques as advances are made in molecular biology. Protein profiles of outer membranes and multilocus enzyme electrophoresis analysis have been used to differentiate strains of *P. vulgaris* and *P. mirabilis* (Kappos et al., 1992). Arbitrarily primed polymerase chain reaction (AP-PCR) and ribotyping have been exploited in a study of *P. mirabilis* isolated in a pediatric hospital (Bingen et al., 1993). With increasing interest in epidemiology, along with expected future simplifications of DNA fingerprinting methods, it is anticipated that more studies will be undertaken to advance our understanding of the epidemiology of these pathogens.

Early studies have shown that *Proteus* strains are widely distributed in nature, occurring in manure, soil, and polluted water, where they are believed to have important roles in the decomposition of organic matter (Wilson and Miles, 1975). They are also present in the intestinal contents of both wild and domesticated animals as well as in the intestines of patients and healthy humans. Incidences of 17–24% for *P. mirabilis* and 3–5% for *P. vulgaris* in healthy humans have been reported (Rustigian and Stuart, 1945; Krikler, 1953). These results were obtained without knowledge that *P. penneri* existed in the genus. Special notice of indole-negative strains was usually not taken, as these would have been considered as atypical indole-negative *P. vulgaris* or atypical ornithine decarboxylase-negative *P. mirabilis* (Müller, 1986a). Thus, their strains identified as *P. vulgaris* may or may not have included *P. penneri* strains. It is noteworthy that in a recent study of bacteria in fecal and urine contaminated bedding in calf-rearing units, *P. vulgaris* and *P. mirabilis*, but no *P. penneri*, strains were isolated (Hawkey et al., 1986b). It seems premature, therefore, to assume that the distribution of *P. penneri* in nature is similar to that of *P. vulgaris*. However, it has been found that *P. penneri* does occur in human feces. Müller (1986a) isolated 13 (0.9%) *P. penneri* from 1422 healthy humans and 20 (1.6%) from 1271 patients. The ecological importance of *Proteus* in the intestine is not known. The hydrolysis of urea is probably minor in comparison to that produced by the large population of urease-producing anaerobes (Sabbaj et al., 1970; Brown et al., 1971), but the oxidative deamination of amino acids may be significant (Drasar and Hill, 1974).

Other human sites of *Proteus* carriage include the urinary tract, the groin area, the vagina, and the prepuce of male infants. The high carriage rate in the intestine has been implicated in the colonization of the groin area (Ehrenkranz et al., 1989) and subsequent development of autoinfections and cross-infections of the urinary tract (Burke et al., 1971). Urine may be considered a habitat of *Proteus* and the source of hospital acquired infections (Hickman and Farmer, 1976; Warren, 1996). The carriage of *Proteus* in the maternal vagina is reported be the source of neonatal infections (Bingen et al., 1993). The carriage of *P. mirabilis* in the prepuce of the infant is believed to be the source of infections in male babies (Glennon et al., 1988).

P. myxofaciens has been isolated only from living and dead gypsy moth larvae (*Porthetria dispar*), but a role in the production of disease in these insects has not been established (Cosenza and Podgwaite, 1966).

Enrichment and Isolation Procedures

Isolation media in the clinical laboratory are formulated to inhibit the swarming of *Proteus* spp. and to select the well-known pathogens such as *Salmonella* and *Shigella*. Such media are suitable for the isolation of *Proteus* spp., but special media for the primary isolation of *Proteus* spp. have been designed (Zarett and Doetsch, 1949; Malinowski, 1966; Xilinas et al., 1975; Hawkey et al., 1986a).

For enrichment of *Proteus* species in fecal samples, tetrathionate or selenite broth have been found to increase the rate of isolation of *P. mirabilis* from 8.2% to 23.6% and *P. vulgaris* from 0% to 2.7% when enrichment preceded plating (Hynes, 1942; Rustigian and Stuart, 1945).

Maintenance Procedures

Proteus strains may be maintained on trypticase soy agar at 4°C with monthly transfers or may be preserved indefinitely by lyophilization. At the Centers for Disease Control and Prevention, cultures in tubes of blood agar base or trypticase soy agar sealed with a cork or rubber stopper remain viable at room temperature for many years without transfer (J.J. Farmer and F.W. Hickman, personal communication).

Differentiation of the genus *Proteus* from other genera

Key characteristics for differentiating the genera *Proteus*, *Providencia*, and *Morganella* are shown in Table BXII.γ.254.

Differentiation of the species of the genus *Proteus*

The key differentiating characteristics for the four species of the genus *Proteus* are shown in Table BXII.γ.255. Additional characteristics of the species are provided in Table BXII.γ.256.

List of species of the genus Proteus

1. **Proteus vulgaris** Hauser 1885, 12[AL] emend. Brenner, Hickman-Brenner, Holmes, Hawkey, Penner, Grimont and O'Hara 1995, 870.
vul.ga'ris. L. adj. *vulgaris* common.

Morphological characteristics as described for the genus. Other characteristics are listed in Tables BXII.γ.254, BXII.γ.255, and BXII.γ.256. Since the last edition of the *Manual*, indole-negative strains formerly classified as *P. vulgaris* biogroup 1 have been assigned to a new species, *Proteus penneri*. *P. vulgaris* at present includes two biogroups. Biogroup 2 strains are positive for indole, salicin, and esculin and have other reactions characteristic of the vast majority of strains in the species. The present type strain and a very small heterogeneous group belong to biogroup 3, which is indole positive but negative in both the salicin and esculin reactions. Additional species will probably be identified in these biogroups.

Some strains are hemolytic on blood agar. Generally resistant to penicillins and cephalosporins. Generally more resistant to antibiotics than *P. mirabilis*. Causes infections of the human urinary tract and other sites but not as frequently as *P. mirabilis*. Widely distributed in nature, occurring in human and animal intestines and in contaminated soil and water.

The mol% G + C of the DNA is: 39.3 ± 1.2 (T_m) (Falkow et al., 1962).

Type strain: ATCC 29905, DSM 13387.

2. **Proteus mirabilis** Hauser, 1885, 34.[AL]
mi.ra'bi.lis. L. adj. *mirabilis* wonderful.

Morphological characteristics are as described for the genus. Other characteristics are listed in Tables BXII.γ.254, BXII.γ.255, and BXII.γ.256. Characteristically indole and maltose negative and ornithine decarboxylase positive. Some strains are hemolytic on blood agar. More frequently isolated from clinical specimens than *P. vulgaris*. Most common site of infection is the human urinary tract. Generally susceptible to penicillins and cephalosporins and more susceptible than *P. vulgaris*.

The mol% G + C of the DNA is: 39.3 ± 1.45 (T_m) (Falkow et al., 1962).

Type strain: ATCC 29906.

GenBank accession number (16S rRNA): AF008582.

3. **Proteus myxofaciens** Cosenza and Podgwaite 1966, 188.[AL]
myx.o.fac'i.ens. Gr. fem. n. *myxa* slime; M.L. masc. n. *faciens* producing; *myxofaciens* slime-producing (bacteria).

Morphological characteristics as described for the genus. Other characters are listed in Tables BXII.γ.254, BXII.γ.255, and BXII.γ.256. Only one isolate studied in detail. Thin film of growth on solid media. Produces highly viscous slime when cultured in trypticase soy broth. Hemolytic on blood agar. Isolated from living and dead gypsy moth larvae (*Porthetria dispar* L).

The mol% G + C of the DNA is: not determined.

Type strain: ATCC 19692.

4. **Proteus penneri** Hickman, Steigerwalt, Farmer III and Brenner 1983, 438[VP] (Effective publication: Hickman, Steigerwalt, Farmer III and Brenner 1982c, 1100.)
penn.er′i. M.L. gen. n. *penneri* of Penner; named after the Canadian microbiologist J.L. Penner.

Morphological characteristics are as described for the genus. Other characteristics are listed in Tables BXII.γ.254, BXII.γ.255, and BXII.γ.256. Formerly classified as *P. vulgaris* biogroup 1. Strains are characteristically negative in indole, maltose, salicin, and esculin reactions. Some strains are hemolytic on blood agar. A pathogen of the human urinary tract. Very resistant to chloramphenicol.

The mol% G + C of the DNA is: 38 (T_m).

Type strain: ATCC 33519, CDC 1808-73.

Genus XXX. **Providencia** *Ewing 1962, 96[AL]*

JOHN L. PENNER

Pro.vi.den′ci.a. M.L. fem. n. *Providencia* Providencia, named after the city of Providence, Rhode Island, U.S.A.

Straight rods, 0.6–0.8 × 1.5–2.5 µm, conforming to the general definition of the family *Enterobacteriaceae.* Gram negative. Motile by peritrichous flagella. They are **facultatively anaerobic**, chemoorganotrophic, having **both a respiratory and a fermentative type metabolism**. Optimal growth temperature is 37°C. **Oxidatively deaminate phenylalanine and tryptophan**. **Acid is produced from D-mannose**. **All except *Providencia rustigianii* produce acid from one or more of the following polyhydric alcohols**: inositol, D-mannitol, adonitol, D-arabitol, and erythritol. Except for *Providencia heimbachae* all are indole positive. Tartrate (Jordan) is utilized by all but a few strains of *P. heimbachae.* Simmons citrate is utilized by all species except *P. heimbachae* and some strains of *P. rustigianii.* Isolated from diarrhetic stools, urinary tract infections, wounds, burns, bacteremias, and contaminated environmental sources. DNA relatedness tests have shown that *Providencia* are more closely related to *Proteus vulgaris* and *Proteus mirabilis* than to other members of the family *Enterobacteriaceae.* Although 16S RNA sequence data are not available for the *Providencia* species, the close relationship of *Providencia* to *Proteus* indicates that *Providencia*, like *Proteus*, belongs to the *Gammaproteobacteria* within the family *Enterobacteriaceae.*

The mol% G + C of the DNA is: 39–42 (Falkow et al., 1962).

Type species: **Providencia alcalifaciens** (de Salles Gomes 1944) Ewing 1962, 96 (*Eberthella alcalifaciens* de Salles Gomes 1944, 183; *Proteus inconstans* (Ornstein 1921) Shaw and Clarke 1955, 155.)

FURTHER DESCRIPTIVE INFORMATION

Since the last edition of the *Manual*, the genus has been extended to include two new species, *P. rustigianii* and *P. heimbachae.* All *Providencia* species, like those of *Proteus* and *Morganella*, deaminate phenylalanine and other amino acids to produce α-keto and α-hydroxycarboxylic acids (Bernheim et al., 1935; Stumpf and Green, 1944; Singer and Volcani, 1955). The carboxylic acids that actively bind iron have siderophore activity (Drechsel et al., 1993). A probe for the amino acid deaminase (*aad*) of *Proteus mirabilis* does not hybridize with DNA from *Providencia* and *Morganella* strains, indicating unrelatedness of the deaminases of these three genera (Massad et al., 1995). In the clinical laboratory, tests for phenylalanine deaminase are commonly used to identify strains belonging to these three genera (Henriksen, 1950; Thibault and Le Minor, 1957).

Providencia, like *Proteus* and *Morganella*, decomposes tyrosine to produce a clearing on the agar medium in which the insoluble amino acid is incorporated (Sheth and Kurup, 1975) and produces a reddish-brown pigment on nutrient agar containing 5% tryptophan (Polster and Svobodová, 1964) or other aromatic amino acids (Müller et al., 1986). *Providencia* species, with the exception of *P. rustigianii*, differ from *Proteus* and *Morganella* in their ability to produce acid from inositol and straight-chain tetra-, penta-, or hexahydroxy- alcohols, and the species are differentiated based on their reactions on these substrates. *Providencia rettgeri* is the most noted for this property, as most strains of the species are capable of producing acid from several or all of these polyhydric alcohols (Penner et al., 1975). In contrast, *P. rustigianii* strains do not produce acid from any of the polyols. Yellowish orange-centered colonies are known to be produced on deoxycholate citrate agar by *P. alcalifaciens*, *P. rettgeri*, and *P. stuartii* (Cook, 1948; Buttiaux et al., 1954). *P. heimbachae* and *P. rustigianii* have not been examined for this property. The color is apparently caused by the precipitation of ferric hydroxide because of the alkalinity produced by the growth of the bacteria on the medium (Catsaras et al., 1965).

Urease is produced characteristically by strains of *P. rettgeri* and variably by strains of *P. stuartii* (Penner et al., 1976c; Farmer et al., 1977; Mobley et al., 1985). In a hospital outbreak of urinary tract infections, some patients were found to be infected with both urease-positive and urease-negative strains of *P. stuartii* (Penner et al., 1976c). The proportion of the urease-positive strains in *P. stuartii* has been estimated to be as low as 15–16% (Brenner et al., 1978; Penner et al., 1979b) and as high as 24% and 30% (Mobley et al., 1985; Mobley et al., 1986a). The urease enzyme of at least some *P. stuartii* strains was found to be transmissible (Grant et al., 1981) on an 82-kb plasmid (Mobley et al., 1986b). Its molecular weight has been estimated to be 375,000 ± 35,000 (Mobley et al., 1986b). The presence of the plasmid in endemic strains of some hospitals could be the cause of variations among hospitals in the frequencies of isolations of urease-positive *P. stuartii* (Penner et al., 1979b) and the failure to identify the species correctly with commercial identification systems (Cornaglia et al., 1988). A key test for separating *P. stuartii* from *P. rettgeri*, particularly from those aberrant *P. rettgeri* in fermenting D-arabitol or erythritol or both, is the fermentation of trehalose (Fischer et al., 1989). Of the *Providencia* species, only *P. stuartii* strains ferment this compound, and thus the test serves to separate this species from others of the genus.

The production of indole is an important test in the identi-

fication of *Providencia*. All species give positive reactions in this test except *P. heimbachae* (Müller et al., 1986). However, it should be noted that strains of *P. heimbachae* may produce positive reactions after 1 d of incubation when tryptone or peptone media with 0.1% tryptophan are used (Müller, 1986b). To avoid false-positive reactions tryptone media without added tryptophan has been recommended (Müller, 1986b).

Although the strains of *Providencia* are cited as unable to produce acid from lactose, some variants have been reported. An unusual strain of *P. rettgeri* that fermented lactose was reported to be associated with an outbreak of nosocomial urinary tract infection (Traub et al., 1971) and a group of 31 lactose positive isolates of *P. rettgeri* were obtained from hospitalized patients with urinary tract infections (Richard et al., 1974). In the latter study, it was found that the lactose-positive trait was not transferable by conjugation. Five lactose-positive strains were also identified among a collection of 699 *P. stuartii* obtained from urinary tracts of catheterized patients (Mobley et al., 1985). The lactose fermentation was transferable by a 150-kb plasmid (Mobley et al., 1985). In addition to urease and lactose fermentation, acid production from sucrose has also been shown to be plasmid-mediated in *P. stuartii*, indicating that variants in this species are more likely to be the results of plasmid-encoded traits than is generally recognized (Mobley et al., 1985).

Antigenic structure Like other Gram-negative species, *Providencia* possesses the surface arrays of antigenic molecules that may serve as markers for differentiation of the strains. The lipopolysaccharide (O) antigens have been the most widely used for serotyping. The original serotyping scheme for *Providencia* included both *P. alcalifaciens* and *P. stuartii* and recognized 56 O antigens, 28 flagellar (H) antigens, and two capsular (K) antigens (Ewing et al., 1954). The O serotyping scheme has since been separated according to species and extended, so that currently 46 O antigens for *P. alcalifaciens* and 17 O antigens for *P. stuartii* may be identified (Penner et al., 1976b, 1979a, b). The original scheme proposed for serotyping *P. rettgeri* listed 34 O antigens and 26 H antigens (Namioka and Sakazaki, 1958). The O serotype reference strains (serostrains) of this scheme were included in a revised and extended scheme that currently recognizes 93 O specificities (Penner et al., 1974, 1976a). In the schemes for O serotyping the three *Providencia* species by Penner and colleagues, the passive (indirect) hemagglutination technique was used instead of the slide agglutination technique to identify the O antigens because it provided greater specificity, sensitivity, and reproducibility of results. This is due to the 228-kDa lipoglycoprotein receptor on the erythrocyte membrane that binds lipopolysaccharide specifically and does not bind proteins or polysaccharides (Springer et al., 1973). Thus, the possible participation in passive hemagglutination of flagellar, fimbrial, or capsular antigens is largely excluded from the antigen-antibody reactions. The O serotyping schemes have been applied in a number of epidemiological investigations and in the study that advocated the reassignment of the *P. rettgeri* biogroup 5 strains to *P. stuartii* (Penner et al., 1975; Penner and Hennessy, 1977). At present, serotyping schemes for *P. heimbachae* and *P. rustigianii* have not been developed. However, three strains of *P. rustigianii*, NCTC 9259, NCTC 9195, and NCTC 9235, originally classified as *P. alcalifaciens* biogroup 3 (Ewing et al., 1972), were included in the present serotyping scheme for *P. alcalifaciens* as the reference strains for serotypes O:10, O:14, and O:54, respectively (Penner et al., 1976b). Strains of these serotypes have not been identified in any epidemiological study on *Providencia* (Penner et al., 1979a).

Although it is highly probable that strains of the same O serotype from the same epidemiological setting are the same and thus important for investigating outbreaks, strains from different sources that have the same O antigens may not be the same. In such cases, a second method of discriminating between isolates is necessary. Using plasmid content to differentiate strains of *P. rettgeri*, it was shown that environmental strains of serotype O:58 were not identical (Hawkey et al., 1986b).

Although flagellar (H) antigens have been defined for some of the serotype reference strains of *P. alcalifaciens* and *P. stuartii* (Ewing et al., 1954) and for some *P. rettgeri* (Namioka and Sakazaki, 1958; Penner and Hinton, 1973), practical use of H typing has been limited to a few isolates examined in the earlier studies. Capsular antigens have also not been used as biomarkers for differentiating strains of this genus. One capsular antigen of *P. rettgeri* has been examined and found to be unlike the typical K antigens of *Enterobacteriaceae* (Namioka and Sakazaki, 1959). It is different in that it retains antibody-binding capacity after heat treatment at 100°C for 1 h and the antigenic specificity is restricted to particular O groups. The authors proposed the designation of C to distinguish this capsular antigen from the *Escherichia coli* L and B antigens and suggested that there are numerous serological types of C antigens.

Numerical analysis of electrophoretic protein patterns Serotyping based on the O antigens has its drawbacks for routine work in the clinical laboratory, because large numbers of commercially unavailable antisera are required. A promising alternative to serotyping is the application of high resolution polyacrylamide gel electrophoresis (PAGE) of proteins combined with computerized analysis of patterns This approach has been used successfully to determine the PAGE types among strains of *P. alcalifaciens*, *P. rettgeri*, *P. stuartii*, and *P. rustigianii* (Costas et al., 1987, 1989, 1990; Holmes et al., 1988). No strains tested by this procedure were serotyped, and although the two methods have not been correlated, the results obtained by determination of the PAGE types suggest the method is as discriminating as serotyping (Costas et al., 1990). Moreover, computerized analysis of electrophoretic protein patterns correlate well with DNA relatedness studies.

Other methods of differentiating strains of *Providencia* species Results have been shown that rDNA fingerprinting also permits discrimination among strains of *P. stuartii* and their differentiation from other species of *Providencia* and *Proteus* (Owen et al., 1988).

Another alternative to serotyping is to discriminate among strains based on their sensitivity and resistance to bacteriocins. An extensive scheme employing 12 bacteriocins (provicines) to discriminate among isolates of *P. alcalifaciens* and *P. stuartii* demonstrated that 37 sensitivity patterns occurred among 300 isolates of these two species, most of which were *P. stuartii* (Al-Jumaili and Fenwick, 1978). One provicine sensitivity pattern accounted for 32 (~10%) of the isolates, seven patterns accounted for ~40%, and the remaining 29 patterns accounted for 40%. The number of patterns and the distribution of the isolates among the different patterns indicated that this system of typing would be applicable in epidemiological investigations of *Providencia* infections caused by these two species.

Fimbriae and hemagglutination In *Providencia*, as in other *Enterobacteriaceae*, fimbriae of different types are present but their distribution is more complex than in most other genera of the family (Old and Adegbola, 1982). The presence of six different types is demonstrable by electron microscopy. The *Providencia* fimbriae that have been examined in most detail are those of *P. stuartii* (Old and Scott, 1981; Old and Adegbola, 1982; Mobley et al., 1988). Three fimbrial types have been examined for hemagglutinating and adhesive properties. Cells expressing mannose-sensitive (MS) type 2 fimbriae agglutinate guinea pig erythrocytes in the absence but not in the presence of mannose. Mannose-resistant, *Klebsiella*-like (MR/K) type 3 fimbriae agglutinate only tannic acid-treated cells, and mannose-resistant, *Proteus*-like (MR/P) type 4 fimbriae agglutinate both tannic acid-treated and untreated erythrocytes. Evidence suggests that the MR/K fimbriae of this species enable binding to catheter material, an important factor in contributing to its long-term persistence in the urinary tract of infected patients with indwelling catheters (Mobley et al., 1988).

Deoxyribonucleic acid relatedness of *Providencia* species *Providencia* are most closely related to *Proteus*, but both genera are only distantly related to *E. coli* and to other species in the family *Enterobacteriaceae* (Coetzee, 1972; Brenner et al., 1978; Brenner, 1984a). In the biochemical characterization of *P. alcalifaciens* four biogroups were recognized (Ewing et al., 1972). DNA relatedness tests showed that biogroups 1 and 2 are a homogeneous group, but biogroup 3 strains were found to be only 44–49% related to biogroups 1 and 2 and 26–33% related to *P. stuartii* (Brenner et al., 1978; Hickman-Brenner et al., 1983b). The biogroup 3 strains were transferred from *P. alcalifaciens* and assigned to a new species, *P. rustigianii* (Hickman-Brenner et al., 1983b). Another group of strains isolated mostly from feces of several species of penguins resembled most closely the biogroup 3 strains and were placed in another newly described species, *P. friedericiana* (Müller, 1983). In a subsequent collaborative study between Müller and the group at the Centers for Disease Control and Prevention, DNA hybridization testing showed that strains of *P. friedericiana* are very closely related to *P. rustigianii* and it was concluded that the two groups should be included in the same species (Hickman-Brenner et al., 1986). *P. rustigianii* was described first and the species name was validated before *P. friedericiana* and therefore *P. rustigianii* has priority and is the senior of the two subjective synonyms (Hickman-Brenner et al., 1986).

A biogroup of strains from penguins that were initially included in *P. friedericiana* and one strain listed under the CDC Enteric Group 78 (strain CDC 1519-73) were found to constitute a separate hybridization group and have been assigned to *P. heimbachae*, a newly described species (Müller et al., 1986).

The *P. alcalifaciens* biogroup 4 strains, originally reported to be inositol-negative were found on reexamination to be inositol-positive, a characteristic reaction of *P. stuartii*. They are also highly related to *P. stuartii* and have low levels of relatedness to *P. alcalifaciens*, *P. rettgeri*, and to *Proteus*, and have therefore been transferred to *P. stuartii* (Brenner et al., 1978).

In the earlier classification of the *Proteus-Providencia* group, *P. rettgeri* was included in the genus *Proteus* (Ewing and Davis, 1972b). In a biochemical characterization of this species, five biogroups were recognized (Penner et al., 1975). The biogroup 5 strains are urease-positive, a characteristic reaction of strains in the genus *Proteus*, but in other respects they resemble urease-negative *P. stuartii* (Penner et al., 1975, 1976c; Penner and Hennessy, 1977). On the basis of DNA relatedness tests they were found to be inseparable from *P. stuartii* and to be only 30–35% related to typical *Proteus rettgeri* biogroups 1, 2, and 3 and were therefore transferred to *P. stuartii* (Brenner et al., 1978). DNA of the three strains of *P. rettgeri* biogroup 4 (salicin and rhamnose negative) and other strains that have reactions atypical of *P. rettgeri* biogroups 1, 2, and 3 have not been examined for relatedness.

Antimicrobial susceptibilities New insights into species differences in antimicrobial susceptibilities have been noted since the revisions in the classification of genus *Providencia* in 1978 (Brenner et al., 1978). Studies using earlier classifications included urease-positive *P. stuartii* in collections identified as *Proteus rettgeri* in examining strains for antimicrobial susceptibility. Since the general adoption of the revised classification, it has become evident that, with the exception of a few unusual strains, *P. stuartii* is the most resistant species in the genus *Providencia* and one of the most resistant species in the family *Enterobacteriaceae*. *P. alcalifaciens* is the least resistant, being susceptible to cephalosporins, aminoglycosides, and quinolones, whereas *P. rettgeri* is intermediate to *P. alcalifaciens* and *P. stuartii*. Most strains of *P. rettgeri* are susceptible to gentamicin, tobramycin, and amikacin but are markedly resistant to quinolones. Most strains of *P. stuartii* are resistant to gentamicin, tobramycin, and the quinolones (including ciprofloxacin) but are susceptible to amikacin (Penner and Preston, 1980; Penner et al., 1982; Hawkey and Hawkey, 1984). Strains of *P. stuartii* that are also resistant to carbenicillin (due to a 47-kb plasmid) have also been identified (Hawkey et al., 1985). Some of the newer β-lactams, however, may be useful alternatives to amikacin in the treatment of serious *P. stuartii* infections (Hawkey, 1984). Only 11 strains of *P. rustigianii* and 13 of *P. heimbachae* have been examined for antimicrobial susceptibilities. They generally resemble *P. alcalifaciens* in their susceptibility to cephalosporins and aminoglycosides, but a small number differ in resistance to particular antibiotics (Hickman-Brenner et al., 1983b; Müller et al., 1986). 73% of the *P. rustigianii* are resistant to colistin and 100% and 77% of the *P. heimbachae* are resistant to tetracycline and cephalothin, respectively. However, it should not be concluded that these are characteristic species differences because of the small numbers of isolates that were available for study.

Pathogenicity *P. alcalifaciens* has been isolated from human feces, particularly from those of the pediatric population ever since the organism was first described, but whether this species is an etiological agent of human gastroenteritis is still a matter of debate and speculation. Evidence in support of a pathogenic role is the finding in several studies that the organisms are more frequently isolated from patients with diarrhea than from normal individuals (Prakash et al., 1966; Bhat et al.,1971a, b; Albert et al., 1995a, 1998; Guth and Perrella, 1996). Serotyping has shown that isolates of serotype O:3 are more frequently associated with pediatric diarrheas than are other serotypes, and this serotype is not frequently found in healthy children (Carpenter, 1964; Bhat et al., 1971a, b; Penner et al., 1979a). Other serotypes identified less frequently in human cases of diarrhea are O:12, O:13, and O:22 (Stenzel, 1961; Bhat et al., 1971a). In the earlier studies, examinations were not made for the more recently recognized pathogens such as rotaviruses, campylobacteria, pathogenic *E. coli*, *Yersinia enterocolitica*, and intestinal parasites, and therefore the importance of fecal isolates of *P. alcalifaciens* has remained unclear. If the organisms of this species are not causal agents, it

may be that they merely flourish in the intestinal environment created by known diarrhea-causing agents. However, in an investigation of traveler's diarrhea it was found that 10% of returning travelers had stools positive for *P. alcalifaciens*, whereas only 1.3% of stools from a control population with diarrhea were positive (Haynes and Hawkey, 1989). No well-known pathogens were found in any of the samples that were positive for *P. alcalifaciens*, and the authors cited this observation in support of a role for this species in producing human diarrhea. Moreover, strains of this species isolated from diarrheal stools have been shown to be invasive for HEp-2 cells, to be able to produce diarrhea in adult rabbits with removable ileal ties (RITARD model), and to invade the rabbit intestinal mucosa (Albert et al., 1995a, 1998). In addition, some patients infected only with *P. alcalifaciens* experienced manifestations of invasive diarrhea (Albert et al., 1998). In another study, 50% of the *P. alcalifaciens* strains isolated in pure culture or from stool specimens in which no other enteropathogen was identified, were found to be invasive for HeLa cells (Guth and Perrella, 1996). Most of the invasive strains were isolated from diarrheal stools but the invasive characteristic was not present in all *P. alcalifaciens* strains that were isolated from patients with diarrhea. The production of cytotoxins or enterotoxins could not be detected in the invasive *P. alcalifaciens* isolates and their invasiveness could therefore not be attributed to these well-known virulence factors (Albert et al., 1995a, 1998; Guth and Perrella, 1996). It should be noted that an *E. coli* strain that can colonize the small bowel mucosa is unable to produce any of the well-known toxins, but can cause fluid accumulation and diarrhea in the rabbit model (Wanke and Guerrant, 1987). The mechanisms for the production by the *E. coli* strain of the fluid and diarrhea are unknown but the possibility of similar, yet unknown mechanisms, should be considered before discounting an etiological role in the enteropathogenicity of at least some strains of *P. alcalifaciens*. Although evidence is accumulating in support of an etiological role, more direct studies are necessary to provide convincing evidence for the inclusion of this species as a true member of the human enteropathogens.

The urinary tract of the compromised or catheterized patient is the most common site of *P. rettgeri* and *P. stuartii* infections. The rise in importance of these two species is associated with their tendency to cause nosocomial infections and with their marked resistance to numerous antibiotics (Wenzel et al., 1976; Whiteley et al., 1977; Kopf and Freitag, 1979; Penner et al., 1979b, 1981; Kocka et al., 1980; McHale et al., 1981; Warren et al., 1982; Hollick et al., 1984; Warren, 1986). Of the two species, *P. stuartii* is significantly more pathogenic and more resistant (Hawkey, 1984). Earlier studies on *P. rettgeri* often included urease-positive *P. stuartii* strains, thus occluding the significant differences between the two species (Lindsey et al., 1976; Penner et al., 1979b). Since the revision in classification, *P. stuartii* have been the subject of numerous studies to determine the basis of their pathogenicity. It has been shown that the majority of the *P. stuartii* isolated from urinary tract infections adhere to uroepithelial cells *in vitro*, suggesting that this property may account for the persistence of the bacteria in the urinary tract (Mobley et al., 1986a). Further studies have yielded evidence that strains bearing the MR/K fimbriae (mannose-resistant *Klebsiella*-like hemagglutinins) have the exceptional ability of binding to catheters, a characteristic that has been hypothesized to enhance their resistance to antimicrobials and to increase the duration of infection in patients with urinary tract catheters (Mobley et al., 1986a). *P. stuartii* can cause serious infections in surgical and burn wounds and often give rise to fatal septicemias (Curreri et al., 1973; Milstoc and Steinberg, 1973; Wenzel et al., 1976).

In elderly catheterized patients who often have high levels of urinary indoxyl sulfate and have colonization of their urinary tract with *P. stuartii*, the urinary catheter bag develops an intense purple color. This purple urine bag syndrome has been determined to be due to the presence in the organisms of indoxyl sulfatase activity, which produces indigo through the decomposition of the urinary indoxyl sulfate (Dealler et al., 1988).

Although *P. stuartii* has been isolated from human feces, there is no evidence that the species causes infections of the human gastrointestinal tract, but in an investigation of neonatal diarrhea in calves (calf scours), evidence was obtained that suggested an etiological role for *P. stuartii* (Waldhalm et al., 1969) or a contributing role by acting synergistically with a neonatal calf diarrhea virus in the production of such diarrheas (Waldhalm et al., 1974b).

P. rustigianii strains have been isolated from human feces, but only infrequently. In a collection of 891 *Providencia* isolates made by Ewing et al. (1972), only 11 (<2%) were identified as *P. rustigianii* and three of these were reported to have been isolated from stool cultures (Hickman-Brenner et al., 1983b). Of the 19 isolates of this species studied by Costas et al. (1987), 10 were also from human feces (Costas et al., 1987). These studies indicate that bacteria of this species can colonize the human intestinal tract, but the clinical significance of this is not known. Strains of this species were also isolated from penguin feces by Müller (1983), but the significance of the presence of these organisms in the intestine to the health of the animals has not been investigated.

All 13 isolates of *P. heimbachae* that have been studied are from healthy penguins except one isolate that was obtained from an aborted bovine fetus (Müller et al., 1986). The medical and veterinary importance of these organisms remains unknown.

Habitats Early studies to determine the habitats of the *Providencia* were carried out without the advantage of the recently revised classifications, and the prevailing view was that these organisms are widespread in nature, occurring in the intestines of various animals and polluted environmental sources (Müller, 1972). Uncertainty remains on the significance of their presence in the human intestine and only recently have systematic studies been reported to address this issue. From examinations of 1108 stool cultures of pediatric patients 56 isolates of *P. alcalifaciens* were found, and in the same period of time 25 isolates were recovered in routine from three adult hospitals (Penner et al., 1979a). Clearly organisms of this species can be found in the human intestine without special enrichment techniques, but their association with the production of diarrhea remains to be demonstrated.

It has been suspected that *P. stuartii* may also be found in the human intestine, but it is rarely isolated in the clinical laboratory from stool samples. As shown in two studies using special techniques such as pre-enrichment or selective differential media, the organisms of this species occur in the human intestine more frequently than previously believed and may be an important and previously underestimated nosocomial reservoir (Hawkey et al., 1982a, b; Stickler et al., 1985). The major source of the organisms in the hospital setting was found to be the colonized skin of the groin area of patients that were fecal carriers of *P. stuartii* (Stickler et al., 1985). *P. stuartii* was not isolated from raw

sewage and sewage contaminated water samples (Stickler et al., 1985). In a survey of the *Proteus*, *Providencia*, and *Morganella* in the environment of calf rearing units, 127 isolates were recovered of which 50 were *Providencia* (Hawkey et al., 1986b). One was classified as *P. alcalifaciens*, 35 as *P. rettgeri*, and 14 as *P. stuartii*, and it was suggested that a potential cause of colonization of the human intestine by these organisms is the consumption of meat (Hawkey et al., 1986b).

P. rettgeri was first isolated by Rettger from poultry (Hadley et al., 1918). Its occurrence in the intestines of reptiles, frogs, and a duck, and its presence in natural waters have been reported (Müller, 1972; Penner and Hennessy, 1979a). Of 112 isolates collected from the clinical laboratory of a large hospital, 106 were from urine specimens and six were from stool samples (Penner and Hennessy, 1979a). In a study of the environment of calf rearing units in England, *P. rettgeri* was found to be second to *Proteus vulgaris* as the most frequently occurring species (Hawkey et al., 1986b). It thus appears that the species is widely distributed in nature, but is not a common resident of the human intestinal tract.

Studies to determine the habitats of *P. rustigianii* and *P. heimbachae* have not been conducted. In the first description of *P. rustigianii* only 11 isolates were available. Three of these were isolated from stools, but the sources of the other eight isolates are unknown (Hickman-Brenner et al., 1983b). Another group of *P. rustigianii* isolates (originally classified as *P. friedericiana*) were all isolated from feces of different species of penguins (Müller, 1983). Strains of *P. heimbachae* have been isolated only from fecal specimens of penguins and from one aborted bovine fetus (Müller et al., 1986).

Enrichment and Isolation Procedures

Media used in the clinical laboratory for isolation of *Enterobacteriaceae* may be used to isolate *Providencia*. Tetrathionate or selenite broths may be used for enrichment.

A selective differential medium for the detection of *P. alcalifaciens* has been developed by Senior (1997). After enrichment of fecal samples in tetrathionate broth, the broth cultures are plated on a solid agar medium that contains phenol red dye and three sugars (xylose, mannitol, and galactose) that *P. alcalifaciens* does not ferment. Since other enteric bacteria that are present in the tetrathionate broth ferment one or more of these sugars, they produce lemon-yellow (acid-forming) colonies. Because strains of *P. alcalifaciens* do not ferment sugars in this medium, the strains produce red (alkaline) colonies.

Enrichment in heart infusion broth (2.5%) followed by plating on MacConkey agar containing 5 mg/l gentamicin sulfate has been found useful for the isolation of *P. stuartii* (Hawkey et al., 1982b). A selective differential medium for *P. stuartii* contains colistin (as the selective agent) and inositol in a nutrient agar base with bromothymol blue (as the acid-alkali indicator). After overnight incubation at 37°C, *P. stuartii* produces yellow inositol-fermenting colonies, *Proteus mirabilis* produces green-centered colonies, and *Morganella morganii* produces blue colonies (Stickler et al., 1985).

Maintenance Procedures

Providencia strains may be maintained on trypticase soy agar at 4°C with monthly transfers or may be preserved indefinitely by lyophilization. The Enteric Section, Centers for Disease Control and Prevention, stores cultures at room temperature in tubes of blood agar base or trypticase soy agar. These tubes are sealed with a cork or rubber stopper, and the cultures have remained viable for many years without transfer (J.J. Farmer III and F. Hickman-Brenner, personal communication).

Differentiation of the genus *Providencia* from other genera

Characteristics and biochemical reactions for differentiating *Providencia* from the closely related genera, *Proteus* and *Morganella*, are described in Table BXII.γ.254 in the chapter on the genus *Proteus*. An important distinguishing characteristic of the *Providencia* (except *P. rustigianii*) is the ability to produce acid from one or more polyhydric alcohols. Biochemical reactions for differentiating *Providencia* from other species in the family *Enterobacteriaceae* are provided in Tables BXII.γ.193, BXII.γ.194, BXII.γ.195, and BXII.γ.196 in the chapter on *Enterobacteriaceae*.

Taxonomic Comments

Since the last edition of the *Manual*, two new species have been included in the genus *Providencia*. Strains formerly classified as *P. alcalifaciens* biogroup 3 (Ewing et al., 1972) were found to constitute a separate species based on DNA relatedness tests and were assigned the epithet *rustigianii* in honor of Robert Rustigian who is noted for his early work on the genus *Proteus* (Hickman-Brenner et al., 1983b). A group of well-defined strains isolated from fecal samples obtained from penguins were found to represent a new species of the genus, and the epithet *friedericiana* was proposed to recognize the technical contributions of Friederike Heimbach (Müller, 1983). Both of these species gained standing in nomenclature but studies of strains exchanged between the two laboratories led to the finding that the species were the same. Since *P. rustigianii* was validated earlier it has priority and *P. friedericiana* is therefore a (junior) subjective synonym of *P. rustigianii* (Hickman-Brenner et al., 1983b). A biogroup of *P. friedericiana* and a strain (CDC 1519-73) of the "Enteric Group 78" were found in DNA relatedness tests to constitute a separate species that has been assigned the epithet *heimbachae* in honor of Friederike Heimbach, who isolated the original 12 strains of this species (Müller et al., 1986).

List of species of the genus Providencia

1. **Providencia alcalifaciens** (de Salles Gomes 1944) Ewing 1962, 96[AL] (*Eberthella alcalifaciens* de Salles Gomes 1944, 183; *Proteus inconstans* (Ornstein 1921) Shaw and Clarke 1955, 155.)
al.cal.i.fac′i.ens. Fr. n. *alcali* alkali; L. v. *facere* to do, make; L. part. adj. *faciens* making; M.L. part. adj. *alcalifaciens* alkali-producing.

The characteristics are as described for the genus and as listed in Tables BXII.γ.257 and BXII.γ.258. Urease negative. Most strains are susceptible to penicillins, cephalosporins, and aminoglycosides. Organisms are generally isolated from diarrheic stools but also from some normal stools. The species is suspected to be a causal agent of infant diarrhea and has been implicated as a cause of traveler's diarrhea but firm evidence for an etiological role in the production of diarrhea has not been established.

The mol% G + C of the DNA is: 43 (T_m) (Owen et al., 1987).

Type strain: ATCC 9886, DSM 30120.

2. **Providencia heimbachae** Müller, O'Hara, Fanning, Hickman-Brenner, Swenson and Brenner 1986, 255.[VP]
heim.bach′ae. M.L. gen. fem. n. *heimbachae* of Heimbach, named to honor Friederike Heimbach who isolated the 12 original strains of the species.

The characteristics are as described for the genus and as listed in Tables BXII.γ.257 and BXII.γ.258. It can be differentiated from other *Providencia* species by its negative reactions for Simmons citrate, growth in the presence of KCN, acid production from trehalose, urease, and indole production, and by positive tests for acid production from adonitol, D-arabitol, D-galactose, and L-rhamnose. Generally susceptible to penicillins, cephalosporins, and aminoglycosides, but most strains are resistant to cephalothin and tetracycline. Only 13 strains have been available for study. All were isolated from healthy penguins except for one that was isolated from an aborted bovine fetus. The medical and veterinary significance of these organisms is unknown.

The mol% G + C of the DNA is: 39.6 (T_m) (Owen et al., 1987).

Type strain: ATCC 35613, DSM 3591.

3. **Providencia rettgeri** (Hadley, Elkins and Caldwell 1918) Brenner, Farmer, Steigerwalt, Klykken, Wathen, Hickman and Ewing 1978, 269[AL] (*Bacterium rettgeri* Hadley, Elkins and Caldwell 1918, 180; *Proteus rettgeri* (Hadley, Elkins and Caldwell 1918) Rustigian and Stuart 1943, 242.)
rett′ge.ri. M.L. gen. n. *rettgeri* of Rettger, named after L.F. Rettger, the American bacteriologist who first isolated the organism in 1904.

The characteristics are as described for the genus and as listed in Tables BXII.γ.257 and BXII.γ.258. Virtually all strains hydrolyze urea and are distinguished from the other *Providencia* by their ability to produce acid from a variety of polyhydric alcohols. Many strains are resistant to the penicillins and cephalosporins, but the strains are generally more susceptible to aminoglycosides than are *P. stuartii* strains. Generally isolated from urine specimens of hospitalized and catheterized patients and less frequently from other sites. May cause nosocomial infections. Rarely isolated from stool specimens.

The mol% G + C of the DNA is: 40.5 (T_m) (Owen et al., 1987).

Type strain: ATCC 29944, DSM 4542.

4. **Providencia rustigianii** Hickman-Brenner, Farmer, Steigerwalt and Brenner 1983a, 673[VP] (Effective publication: Hickman-Brenner, Farmer, Steigerwalt and Brenner 1983b, 1060.)
rus.tig.i.an′i.i. M.L. gen. n. *rustigianii* of Rustigian, named in honor of Robert Rustigian who did early studies on the *Proteus* group.

The characteristics are as described for the genus and as listed in Tables BXII.γ.257 and BXII.γ.258. Strains are differentiated from other *Providencia* species by their production of acid from D-galactose but not from adonitol, *i*-inositol, and trehalose. Only 11 strains have been examined for antibiotic susceptibly. Most are susceptible to cephalosporins and synthetic penicillins but resistant to natural penicillin and colistin. They may colonize the human intestinal tract but the medical significance of this is not known.

The mol% G + C of the DNA is: 41.8 (T_m) (Owen et al., 1987).

Type strain: ATCC 33673, DSM 4541.

iamez 1954) Ewing 1962, 96[AL] (*Proteus stuartii* Buttiaux, Osteux, Fresnoy and Moriamez 1954, 385; *Proteus inconstans* (Ornstein 1921) Shaw and Clarke 1955, 155.)
stu.ar' ti.i. M.L. gen. n. *stuartii* of Stuart, named after C.A. Stuart, American bacteriologist who did much of the early work on *Providencia*.

The characteristics are as described for the genus and as listed in Tables BXII.γ.257 and BXII.γ.258. Highly resistant to antibiotics. Some strains are among the most resistant of the *Enterobacteriaceae*. Strains may be urease positive or urease negative. Isolated most often from urine specimens of hospitalized and catheterized patients. Some strains have the ability to adhere to catheters and thus enhance resistance to treatment and increase the duration of the infection. Less frequently isolated from wounds, burns, and bacteremias. They occur in small numbers in the intestines of some individuals and are rarely isolated routinely from stool cultures in the clinical laboratory but serve as the source for the colonization of the skin of the groin area, which may lead to autoinfections and cross-infections.

The mol% G + C of the DNA is: 40.7 (T_m) (Owen et al., 1987).

Type strain: ATCC 29914, DSM 4539.

Genus XXXI. **Rahnella** *Izard, Gavini, Trinel and Leclerc 1981c, 382[VP] (Effective publication: Izard, Gavini, Trinel and Leclerc 1979, 174)*

Peter Kämpfer

Rah' nel.la. M.L. dim. ending *-ella*; M.L. fem. n. *Rahnella* named after Otto Rahn, the German-American microbiologist and who proposed the name *Enterobacteriaceae* in 1937.

Straight rods 0.5–0.7 × 2–3 μm, conforming to the general definition of the family *Enterobacteriaceae*. **Gram negative, motile by peritrichous flagella when grown at 25°C.** Facultatively anaerobic. Chemoorganotrophic. **Psychrotolerant**, growing at 4°C. D-Glucose is fermented with the production of acid and, for the majority of strains, gas. Nitrate is reduced to nitrite. Oxidase neg-

ative, catalase positive. **Negative for lysine and ornithine decarboxylases and for arginine dihydrolase. Most strains are (weakly) positive for phenylalanine deaminase (after 48 h), methyl red, and Voges–Proskauer reaction. Acids are produced from various carbohydrates, including L-arabinose, cellobiose, lactose, maltose, mannose, L-rhamnose, raffinose, D-xylose, and salicin.** Sequence analyses of the 16S rDNA of four *Rahnella* strains clearly placed the genus within the *Gammaproteobacteria* in the family *Enterobacteriaceae*. Highest 16S rDNA sequence similarity to *Yersinia enterocolitica* ATCC 9610^T (97.7%). By omitting the hypervariable regions V1 and V5 (corresponding to *E. coli* base positions 147–1490; Brosius et al., 1978), *Hafnia alvei* ATCC 13337^T showed the highest sequence similarity (96.63%) to *R. aquatilis* ATCC 33071^T. Most often isolated from fresh water, but also found in the intestine of snails and various other environmental habitats, including soils and the rhizosphere. Can occasionally be isolated from foods or human clinical specimens, including wound infections, bacteremias, feces from patients with acute gastroenteritis, and septicemia, especially from immunocompromised patients. The genus currently includes three genomospecies (*R. aquatilis* [*Rahnella* genomospecies 1], *Rahnella* genomospecies 2, and *Rahnella* genomospecies 3), which cannot be phenotypically differentiated.

The mol% G + C of the DNA is: 51–56.

Type species: **Rahnella aquatilis** Izard, Gavini, Trinel and Leclerc 1981c, 382 (Effective publication: Izard, Gavini, Trinel and Leclerc 1979, 174.)

Further descriptive information

A comparison of the total 16S rDNA sequence of the type strains of *R. aquatilis* with other representatives of the family *Enterobacteriaceae* showed highest similarity (97.7%) with the type strain of *Yersinia enterocolitica*. Eight representative strains representing all three *Rahnella* genomospecies were used for 16S rRNA gene amplification and sequencing (Brenner et al., 1998). The hypervariable regions V1 and V5 were omitted for sequence comparison resulting in a sequence that corresponded to *E. coli* base positions 147–1490 (Brosius et al., 1978). The eight strains showed sequence similarities ranging from 97.7–100% and fell in three distinct groups (Brenner et al., 1998). Three additional strains sequences already deposited in GenBank also grouped with *R. aquatilis* type strain, exhibiting 99.7–100% sequence similarity. The second group contained five strains used in the DNA–DNA relatedness experiments (Brenner et al., 1998), four of which were in genomospecies 2 and one in genomospecies 1 (*Rahnella aquatilis sensu stricto*). Two further strains, for which sequences were deposited in GenBank, were also found in this group. This observation supports the advisability of performing DNA–DNA hybridization experiments on strains showing 97% or greater sequence similarity, before considering them to belong to the same species (Brenner et al., 1998). The third group contained only strain DSM 30078, representing *Rahnella* genomospecies 3.

The phenotypic description of the genus *Rahnella* is largely based on the studies of Gavini et al. (1976a), Izard et al. (1979), Farmer (1984b), Farmer et al. (1985a), Brenner (1992a), and Brenner et al. (1998). In the study of Brenner et al. (1998), a total of 51 *Rahnella* strains were included, and the results indicated that the strains comprise three closely related species (genomospecies), which cannot be differentiated phenotypically. Their subdivision is described below (see Taxonomic Comments).

Rahnella strains grow readily on all kinds of media and no growth requirements have been described. A nutrient-rich medium (e.g., tryptone–soy agar, sheep-blood agar, or nutrient agar) gives best results. Incubation at temperatures ranging from 25–35°C results often in better growth that incubation at 37°C. The majority of strains are psychrotolerant, growing (slowly) at temperatures of 4°C. Growth was reported even at temperatures of 1°C ± 1°C (Davis and Eyles, 1992).

Members of the genus *Rahnella* ferment lactose and produce β-galactosidase (ONPG test). Acid production from D-xylose is observed in parallel with strong β-xylosidase activity. β-glucuronidase is negative in all strains. Indole production, hydrogen sulfide formation, tyrosine deaminase, urease, and DNase tests are negative. Nitrogen fixation (Berge et al., 1991; Kim et al., 1998) and mineral phosphate solubilization (Kim et al., 1998) has been reported in some strains of *R. aquatilis*. Various carbon sources, including carbohydrates, organic acids, and amino acids, are utilized as sole sources of carbon (Brenner et al., 1998).

Isoprenoid quinone Q-8 is the predominant quinone and small amounts of the menaquinone MK-8 are found in *R. aquatilis* ATCC 33071^T (P. Kämpfer, unpublished results). The fatty acid composition as determined by gas chromatographic analysis of all 51 strains used in the study of Brenner et al. (1998) differed only slightly (P. Kämpfer, unpublished results). All strains contained the fatty acids $C_{12:0}$, $C_{14:0}$, $C_{16:0}$, $C_{17:0\ cyclo}$, $C_{19:0\ cyclo}$, summed feature ($C_{16:1\ iso\ I}$ and/or $C_{14:0\ 3OH}$), summed feature ($C_{16:1\ \omega7c}$ and/or $C_{15:0\ iso\ 2OH}$), and summed feature ($C_{18:1\ \omega7c}$, $C_{18:1\ \omega9t}$, and/or $C_{18:1\ \omega12t}$), a fatty acid type typical of a member of the family *Enterobacteriaceae*. The dominant polyamines, as determined by high-performance liquid chromatography, were putrescine and cadaverine (Hamana, 1996). Minor amounts of diaminopropane were found in both strains studied; one strain also contained agmatine, whereas the other contained spermidine.

Members of the genus *Rahnella* are usually sensitive to aminoglycosides, cefotaxime, doxocyline, trimethoprim, gentamicin, tetracycline, and tobramycin, but resistant to chloramphenicol. Susceptibility to β-lactams differs among strains. Antimicrobial susceptibility data are summarized by Funke and Rosner (1995). They state that aminopenicillins and first-generation cephalosporins have only limited activity against *R. aquatilis*, whereas ureidopenicillins and carbapenems are more active. *R. aquatilis* is usually susceptible to aminoglycosides and quinolones. *Rahnella* produces enterobacterial common antigen (Böttger et al., 1987).

The pathogenicity of *Rahnella* in humans and animals is not clearly established. Strains isolated from humans appear to be opportunistic rather than true pathogens.

Rahnella are widely distributed in nature. They may be isolated from foods and occasionally from a wide variety of human sources. The natural habitat of *Rahnella* seems to be water, and all of the isolates of Gavini et al. (1976a) were from waters in France. Several American water isolates have also been identified as *R. aquatilis*. The study of the intestinal content of snails for the presence of *Enterobacteriaceae* (Brenner et al., 1998) resulted in the isolation of infrequently seen enterobacterial species, among them *Rahnella* spp. Rhodes et al. (1998) found *Rahnella* spp. in the intestinal content associated with 12,000-year-old mastodon remains. The study of mountain soils for psychrotrophic *Enterobacteriaceae* resulted in the isolation of *Rahnella* (Horie et al., 1985), and nitrogen-fixing strains were isolated from the rhizosphere of wheat and maize (Berge et al., 1991; Heulin et al., 1994). Heron et al. (1993) found *Rahnella* isolated among enterobacteria associated with grass and silages. The microbiolog-

ical study of prepared salad vegetables and sprouts resulted in the isolation of *Rahnella* (Geiges et al., 1990). In minced meat, fish, and milk, *Rahnella* were frequently encountered by Lindberg et al. (1998), and one fish isolate was found to contain the gene of *E. coli* heat-labile toxin (lt). Hamze et al. (1991) found *R. aquatilis* as a potential contaminant in lager beer breweries. Two strains of *Rahnella* were isolated from buckwheat seeds (Iimura and Hosono, 1996).

R. aquatilis may also occasionally occur in human clinical specimens. The first case reported was a strain from a burn wound (Farmer et al., 1985a). Maraki et al. (1994) reported a surgical wound infection with *Rahnella*. Two *Rahnella* isolates were recovered from the feces of two patients with acute gastroenteritis, one of whom was an AIDS patient (Reina and Lopez, 1996a). The strains were resistant to ampicillin, cephalothin, and cefoxitin. Funke and Rosner (1995) reported *R. aquatilis* bacteremia in an HIV-infected intravenous drug-abuser. Caraccio et al. (1994) isolated *Rahnella* from a bacteremic patient with chronic renal failure. Matsukura et al. (1996) isolated *Rahnella* aquatilis from a blood culture obtained from a case of endocarditis. *R. aquatilis* was found in the blood of a diabetic patient and a patient with laryngeal carcinoma (Oh and Tay, 1995). Both patients recovered from the infection after treatment with parenteral antibiotics. Additional cases were described by Goubau et al. (1988), Harrell et al. (1989), and Hoppe et al. (1993). Literature on *R. aquatilis* infections in humans are reviewed by Alballaa et al. (1992), Maraki et al. (1994), and Funke and Rosner (1995).

Enrichment and Isolation Procedures

Media used for the isolation of *Rahnella* are similar to those used for other members of the family *Enterobacteriaceae*. No specific selective medium is available for *Rahnella* species. As pointed out by Grimont and Grimont (1992), the requirements for a selective medium can be summarized as follows: (1) a precise and stable delineation of the taxon (genus or species); (2) known and stable common nutritional properties uncommon outside the group (genus or species); and (3) a special, in most cases clinical, or public health requirement for such a medium. Because of the low clinical significance and the presence of *Rahnella* in various habitats, the selective isolation of *Rahnella* is rarely required, except for epidemiological studies. In most cases, organisms belonging to the genus *Rahnella* are isolated with differential media not inhibitory for *Enterobacteriaceae*, such as MacConkey agar, bromothymol blue lactose agar, or phenol red lactose agar. *Rahnella* strains grow readily on nutrient-rich media, and no particular growth requirements have been described.

Maintenance Procedures

Rahnella strains can be maintained in tryptone soy agar stabs or on nutrient agar when kept at room temperature in the dark. They can be preserved by storage in broth containing 10% glycerol or in calf or bovine serum at −80°C. Lyophilization seems to be the best procedure for preservation.

Differentiation of the genus *Rahnella* from other genera

The genus *Rahnella* has no single distinguishing feature useful for differentiation from the other genera of *Enterobacteriaceae* (Table BXII.γ.193 of the *Enterobacteriaceae*). *Rahnella* does not produce a yellow pigment, is negative for lysine and ornithine decarboxylases, and is weakly positive for phenylalanine deaminase. These characters may be helpful in differentiation of *Rahnella* from the genera *Pantoea* and *Erwinia*.

Taxonomic Comments

Based on a numerical taxonomic study of *Enterobacteriaceae*, Gavini et al. (1976a) defined a new group within the family and gave it the vernacular name "group H2". Subsequently, Izard et al. (1979) used DNA–DNA hybridization to compare strains of group H2 to each other and to named species of *Enterobacteriaceae*. Based on the close relatedness within group H2 and the low relatedness to other *Enterobacteriaceae*, they proposed the new genus *Rahnella* with one species *Rahnella aquatilis*, and designated a holotype strain. The name *Rahnella* was chosen to honor Otto Rahn, the German-American microbiologist for his many contributions to systematic bacteriology and for his proposal of the family name *Enterobacteriaceae* in 1937. Because all of the isolates investigated by Izard et al. (1979) were from water, the species name *aquatilis* was chosen. The names *Rahnella* and *R. aquatilis* were effectively published (Izard et al., 1979) but were not validated in the *International Journal of Systematic Bacteriology* before 1 January 1980. They did not appear on the Approved Lists of Bacterial Names (Skerman et al., 1980), but both names have now been validly published (Izard et al., 1981c) and have standing in nomenclature. From 1979 to now, *Rahnella* was isolated from various other environmental habitats, including soils and the rhizosphere, and from food, indicating a wide distribution in nature. Furthermore, several clinical isolates were reported, in most cases from immunocompromised patients. Between 1984 and 1988, Müller et al. (1995a, b, 1996) screened the intestinal contents of snails and slugs for the presence of *Enterobacteriaceae* and found several *Rahnella* isolates in addition to the genera *Buttiauxella*, *Kluyvera*, and others. In a subsequent study 51 *Rahnella* and *Rahnella*-like organisms were subjected to an extensive DNA–DNA hybridization study. The results indicated that the strains comprised three closely related (genomo-)species within the genus, one corresponding to *R. aquatilis*. The relative binding ratios obtained from DNA–DNA hybridization studies between the *Rahnella* genomospecies are given in Table BXII.γ.259. For the two new species the vernacular names *Rahnella* genomospecies 2 and *Rahnella* genomospecies 3 were proposed (Brenner et al., 1998). It was not possible to differentiate these genomospecies on the basis of physiological and biochemical tests.

Acknowledgments

I thank Don J. Brenner for his helpful comments and critical reading of this chapter, Hans E. Müller for interesting discussions and furnishing

List of species of the genus Rahnella

1. **Rahnella aquatilis** Izard, Gavini, Trinel and Leclerc 1981c, 382[VP] (Effective publication: Izard, Gavini, Trinel and Leclerc 1979, 174.)

a.qua' ti.lis. L. adj. *aquatilis* living in water.

Represents *Rahnella* genomospecies 1 of the study of Brenner et al. (1998). The characteristics are as described for the genus. Detailed characteristics are given in Table BXII.γ.260.

Occurs in freshwater, but also in environmental habitats like soil. May occasionally be isolated from human clinical specimens; in most cases from immunocompromised hosts. Clinical significance is unknown. Mean DNA–DNA relatedness among the 21 strains studied by Brenner et al. (1998), including 9 of the 10 original water isolates described by Izard et al. (1979) was 88% in 60°C reactions (range 72–100%). Mean relatedness in 75°C reactions was 81% (range 61–100%).

The mol% G + C of the DNA is: 51–56 (T_m).

Type strain: 133, ATCC 33071, CIP 78-65, DSM 4594.

GenBank accession number (16S rRNA): AJ233426.

Other Organisms

1. *Rahnella* genomospecies 2.

This species was proposed on the basis on DNA–DNA hybridization experiments and comprises 30 strains (Brenner et al., 1998). Phenotypically it is indistinguishable from *Rahnella aquatilis*. A combination of the utilization tests with L-histidine, L-ornithine, and L-proline (Table BXII.γ.260; Brenner et al., 1998) may be helpful in differentiation from *Rahnella aquatilis*, but does not allow a clear (genomo)-species identification. All 30 strains studied by Brenner et al. (1998) were 83% or more related in 60°C reactions (range 70–100%). In 75°C reactions the strains were 74% or more related, with one exception showing only 68% relatedness to the labeled reference organism.

Strains were isolated from water, intestinal contents of snails, and clinical material, including stored donated human blood.

Deposited strain: SM S7/1-576.

2. *Rahnella* genomospecies 3.

This species was also proposed based on DNA–DNA hybridization experiments (Brenner et al., 1998) and is represented by a single strain: DSM 30078 (isolated from minced meat). Phenotypically it can be separated from *Rahnella aquatilis* and *Rahnella* genomospecies 2 (Table BXII.γ.260), but without results from different strains one cannot determine whether the results are strain- or species-specific.

Deposited strain: DSM 30078.

Genus XXXII. **Saccharobacter** *Yaping, Xiaoyang and Jiaqu 1990, 412[VP]*

Don J. Brenner

Sac.cha.ro.bac' ter. L. n. *saccharum* sugar; M.L. n. *bacter* a rod; M.L. masc. n. *Saccharobacter* a sugar rod.

Small straight rods, 0.5–0.9 × 1.0–1.0 μm. **Gram negative, motile by peritrichous flagella.** Facultatively anaerobic. Chemoorganotrophic. Colonies on glucose-yeast extract agar are opaque and milky white, smooth, and low convex with entire margins. Oxidase negative, catalase positive. Nonpigmented. Nonsporeforming. No lipid granules present. Optimal growth temperature range is from 30–46°C. **D-glucose is fermented with the production of ethanol, CO_2, and small amounts of acids, but no hydrogen. Indole negative, methyl red positive, Voges–Proskauer test positive, citrate positive**. H_2S production, gelatin hydrolysis, urease, nitrogen reduction, lysine decarboxylase, and ornithine decarboxylase are negative; arginine dihydrolase is delayed positive (4 d). Acid is produced from D-glucose, L-arabinose, esculin, D-fructose, D-galactose, maltose, D-mannitol, melibiose, L-rhamnose, L-sorbose, starch, sucrose, trehalose, D-xylose. Lactose fermentation is delayed positive after 9 d. Dulcitol, gluconate, *myo*-inositol, and raffinose are not fermented. Malonate is used as a sole carbon source; ammonium sulfate, yeast extract, urea, phenylalanine, glutamine, and tryptone serve as sole nitrogen sources, but sodium glutamate does not. Produces β-galactosidase and grows in the presence of KCN. **Grows in the presence of 35% D-glucose and 6% NaCl, but not 40% D-glucose or 8% NaCl.** 16S rDNA sequence has not been determined.

The mol% G + C of the DNA is: 63.5.

Type species: **Saccharobacter fermentatus** Yaping, Xiaoyang, and Jiaqu 1990, 412.

Further descriptive information

Carbohydrates are presumably degraded by the Embden-Meyerhof-Parnas pathway, as indicated by the absence of 6-phos-

phogluconate dehydratase and 2-keto-3-deoxygluconate-6-phosphate aldolase and the presence of fructose diphosphate aldolase. Degrades 1 mol of glucose to approximately 2 mol of ethanol and 2 mol of CO_2.

Maintenance Procedures

Cultures are grown at 30°C and maintained on glucose-peptone-yeast extract agar. Lyophilization is used for long-term storage.

Differentiation of the genus *Saccharobacter* from other genera

Saccharobacter is easily differentiated from *Zymomonas*, another ethanol-producing genus. *Saccharobacter* is peritrichously flagellated, whereas *Zymomonas* has polar flagella. *Zymomonas* ferments only D-glucose, fructose, and sucrose, whereas *Saccharobacter* ferments a number of other carbohydrates (see above). *Zymomonas* degrades sugars by the Entner-Duoderoff pathway, while *Saccharobacter* ferments sugars by the Embden-Meyerhof-Parnas pathway. *Saccharobacter* can easily be differentiated from various species of *Enterobacteriaceae* based on its indole, methyl red, Voges–Proskauer, and citrate (IMViC) reactions, together with its negative nitrate reductase reaction, its positive phenylalanine deaminase reaction, and its sugar fermentation pattern (see chapter on *Enterobacteriaceae*).

Taxonomic Comments

Since 16S rDNA sequencing has not been done on the type species, it is impossible to accurately place the genus *Saccharobacter* phylogenetically. *Saccharobacter* appears to be phenotypically similar to members of the family *Enterobacteriaceae* based on a number of key characteristics. These include negative oxidase and positive catalase reactions, peritrichous flagella, facultatively anaerobic metabolism, and fermentation of D-glucose and other carbohydrates. It differs from *Enterobacteriaceae* in the end products of fermentation, which in *Enterobacteriaceae* are mixed acids or 2,3-butanediol, with no more then 0.5 mol of ethanol from 1 mol of D-glucose. *Saccharobacter* also differs from most, if not all, members of *Enterobacteriaceae* by the high mol% G + C content.

Further Reading

Yaping, J., L. Xiaoyang and Y. Jiaqi. 1990. *Saccharobacter fermentatus* gen. nov., sp. nov., a new ethanol-producing bacterium. Int. J. Syst. Bacteriol. *40*: 412–414.

List of species of the genus Saccharobacter

1. **Saccharobacter fermentatus** Yaping, Xiaoyang and Jiaqu 1990, 412[VP]
fer.men.ta'tus. M.L. adj. *fermentatus* fermentative.

The characteristics are those given for the genus. All extant strains were isolated from squeezed leaf juice of agave. Isolated from squeezed leaf juice of agave in Wuhan, People's Republic of China.

The mol% G + C of the DNA is: 63.5 (T_m).

Type strain: WVB8512.

Genus XXXIII. **Salmonella** *Lignières 1900, 389*[AL]

Michel Y. Popoff and Léon E. Le Minor

Sal.mon.el'la. M.L. *-ella* dim. ending; M.L. fem. n. *Salmonella* named after D.E. Salmon, an American bacteriologist.

Straight rods, 0.7–1.5 × 2.0–5.0 μm, conforming to the general definition of the family *Enterobacteriaceae*. Gram negative. **Usually motile** (peritrichous flagella). Facultatively anaerobic. Colonies are generally 2–4 mm in diameter. Nitrates are reduced to nitrites. **Gas is usually produced from D-glucose.** Hydrogen sulfide is usually produced on triple-sugar iron agar. Indole negative. **Citrate is usually utilized as a sole carbon source.** Lysine and ornithine decarboxylase (Møller's) reactions are usually positive. Urease negative. Phenylalanine and tryptophan are not oxidatively deaminated. Sucrose, salicin, inositol, and amygdalin are usually not fermented. Lipase and deoxyribonuclease are not produced. Pathogenic for humans, causing enteric fevers, gastroenteritis, and septicemia; may also infect many animal species besides humans. Some serovars are strictly host-adapted.

The mol% G + C of the DNA is: 50–53.

Type species: **Salmonella choleraesuis** (Smith 1894) Weldin 1927, 155 (*Bacillus cholerae suis* Smith 1894, 9.)

Further descriptive information

Although most salmonellae are motile, the serovar Gallinarum (or serovar Pullorum) is always nonmotile.

Certain *Salmonella* serovars, such as serovar Abortusovis, may form unusually small colonies (~1 mm diameter), whereas most types form larger colonies (2–4 mm).

Most salmonellae are aerogenic. However, serovar Typhi, an important exception, never produces gas. Anaerogenic variants of normally gas-producing *Salmonella* serovars may occur; this is particularly common with serovar Dublin.

Hydrogen sulfide is produced by most salmonellae, but a few serovars do not produce it (e.g., most strains of serovar Paratyphi A and some strains of serovar Choleraesuis).

Citrate is generally utilized by salmonellae, but some serovars do not use it (particularly host-adapted serovars such as serovar Typhi and serovar Paratyphi A).

The lysine decarboxylase reaction (Møller's) is positive for most salmonellae, but an important exception is serovar Paratyphi A. Most salmonellae are also positive for ornithine decarboxylase reaction (Møller's), but serovar Typhi is negative.

Other biochemical characteristics of the genus are indicated in Tables BXII.γ.193, BXII.γ.194, and BXII.γ.196 in the chapter on the family *Enterobacteriaceae*. Subdivision of the genus *Salmonella* into species and subspecies (Le Minor and Popoff, 1987; Reeves et al., 1989a) based on biochemical characteristics is shown in Table BXII.γ.261. Kauffmann (1960, 1963a, b, 1964) subdivided the genus *Salmonella* into "subgenera" (see Taxonomic Comments). These subdivisions correspond more closely to species or subspecies in other groups of bacteria, but whatever rank is assigned to them, the worthiness of these subdivisions was confirmed by Rohde (1965, 1966, 1967).

[c] Typhimurium d, Dublin −.

Division into serovars The antigenic formulae of *Salmonella* serovars are listed in the Kauffmann–White scheme (Table BXII.γ.262). They are composed of numbers and letters given to the different O (somatic), Vi (capsular), and H (flagellar) antigens. Only those antigens of primary diagnostic importance are indicated in the Kauffmann–White scheme. Antigenic formulae (for example 6,7,[Vi]:c:1,5) represent the O antigenic factors, the Vi capsular antigen when present, the first phase of the H antigen, and the second phase of the H antigen, respectively. Those formulae with major O antigenic factors in common are collected into an O group and arranged alphabetically by the first phase of the H antigen within the group.

Lysogenization by certain converting phages may produce changes in the O antigenic formulae of salmonellae. In groups O:2, O:4, and O:9, presence of O:1 antigenic factor is associated with lysogenization (Iseki and Kashiwagi, 1955, 1957; Zinder, 1957; Stocker, 1958), but presence or absence of this factor in strains of these groups does not change the name of the serovar (for example, serovar Typhimurium applies to both O:1-positive and O:1-negative strains). Factors associated with phage conversion are underlined in the Kauffmann–White scheme. Converting phages of *Salmonella* are identical in morphology (Vieu et al., 1965), but their action is limited to certain O groups and they are serologically different from one another (Le Minor, 1968).

The specificities of O factors in *Salmonella* are determined by the composition and structure of the polysaccharides. Specificity is modified during smooth to rough mutation and by bacteriophage conversions (see reviews by Lüderitz et al., 1971; Stocker and Mäkelä, 1971, 1978). The only difference between the 4,12 and the 9,12 O-specific repeating units is in the di-deoxyhexose branch unit attached to the mannose, which is abequose in O:4,12 and tyvelose in O:9,12. In the conversion of O:3,10 to O:3,15, the terminal acetyl radical of the chain is suppressed and the α-lineage between galactose and mannose is transformed into a β-linkage. Other modifications of the specificity of O antigens may occur after mutation(s), resulting in new specificities called T1 and T2 by Kauffmann (1956) or in different R types (reviewed by Lüderitz et al., 1971; Stocker and Mäkelä, 1971, 1978).

Surface antigens, commonly observed in other members of the *Enterobacteriaceae* family (e.g., *Escherichia coli* and *Klebsiella*), may be found in some *Salmonella* serovars. Surface antigens in *Salmonella* may mask O antigens, and the culture will not agglutinate with O antisera. The Vi antigen is a surface antigen found mainly in serovar Typhi and serovar Paratyphi C, as well as in a few strains of serovar Dublin. Heating at 100°C generally solubilizes Vi antigen, and heat-treated bacteria agglutinate with proper O antisera. Biogenesis of the Vi polysaccharide is governed by a set of genes located at the *viaB* locus, which is specific to Vi-expressing strains. Expression of Vi antigen is controlled by two two-component regulatory systems, OmpR-EnvZ and RcsB-RcsC (reviewed by Virlogeux-Payant and Popoff, 1996). One signal for this complex regulatory control was shown to be osmolarity (Pickard et al., 1994).

Subdivision of serovars Biovars are different sugar fermentation patterns shown by strains of the same serovar. They are determined by the presence or absence of enzymes and hence are genetically determined. Biovars may serve as markers and be of interest epidemiologically (for example, the xylose-positive and xylose-negative character of serovar Typhi).

Phagovars are determined by the sensitivity of cultures to a series of bacteriophages at appropriate dilutions. Phage typing of serovar Typhi and other salmonellae that possess the Vi antigen (serovar Paratyphi C and a few strains of serovar Dublin) is based on a series of adapted phages from phage Vi II of Craigie and Yen (1938). Phage typing of serovar Paratyphi B (Felix and Callow, 1943) and serovar Typhimurium (Anderson, 1964) uses a different series of phages. Analogous methods have been proposed for other serovars of *Salmonella*, some of them making use of the lysogenicity of the strains.

Other subdivisions of serovars may be based on production of, or on sensitivity to, bacteriocins, and on resistance to antibiotics.

[a]Symbols: [ ], O (not underlined) or H factor that may be present or absent without relation to phage conversion, i.e., factor [5] of O:4 (B) group. When H factors are in square brackets, this means that they are exceptionally found in wild strains. For example, most strains of Paratyphi A possess the monophasic antigen phase 1 H:a. In rare cases, diphasic strains with H:1,5 as H antigen phase 2 may be isolated. For this reason, [1,5] is mentioned in square brackets in the formula of this serovar. ( ), O or H factor weakly agglutinable. The factor (k) corresponding to Arizona factor H:22 is weakly agglutinable by k standard serum, but is normally agglutinable by k polyvalent serum. Symbols for somatic factors determined by phage conversion are underlined (example 6, 14,18). They are present only if the culture is lysogenized by the corresponding converting phage. These factors are usually added to the factors present in nonconverted strain (for example 6,7 →6,7,14). In 0:3,10 group, factors 15 or 15, 34 take the place of factor 10. For this reason, these factors are underlined and quoted into square brackets in this group. These underlined factors are mentioned in the table for serovars in which they were found. It is likely that this situation may be encountered for all serovars in the same group O.

[b]The subfactors of O factors—40, 47, 48, and 50—are no longer mentioned, as their identification is unnecessary in current practice. O and H factors having the same symbol in the Kauffmann–White scheme are always related, but not always identical in different serovars. Table BXII.γ.262 of the antigenic formulae of the *Salmonella* is a scheme established for a diagnostic purpose. Details unnecessary for the diagnosis of serovars are not given in this scheme (e.g., R-phase of the H antigen are not indicated).

[c]Names of the serovars of *S. enterica* subsp. *enterica*. For other subspecies of *S. enterica*, the subspecies to which the serovars belong are indicated by the following symbols: II, serovars of *S. enterica* subsp. *salamae*; IIIa, serovars of *S. enterica* subsp. *arizonae*; IIIb, serovars of *S. enterica* subsp. *diarizonae*; IV, serovars of *S. enterica* subsp. *houtenae*; VI, serovars of *S. enterica* subsp. *indica*; V, serovars of *S. bongori* (the symbol "V" was retained to avoid confusion with serovar name of *S. enterica* subsp. *enterica*).

[d]Strains of this group maybe lysogenized by phage 14(O:6,7,→O:6,7,14). The strains possessing O:6,7,14 had been classified in a special group, C4. They are now classified into group C1. Names formerly given to serovars of group C4 are deleted.

[e]Groups O:6,8(C2) and O:8(C3) differentiated only by presence or absence of O:6 factor, were lumped together in a single group O:8.

[f]Strains of this group maybe lysogenized by phage e15 (O:3,10→ O:3,15), then by phage e34 (O:3,15→ O:3,15,34). In these cases, factors O:15 or O:15,34 take the place of factor O:10 which is no longer agglutinable. The strains of O structure O:3,15 were formerly classified in a special group, E2, and the strains of O structure O:3,15,34 in another group, E3. They are now classified with the strains O:3,10 into group E1. Factors O:15 and O:15,34 are given in square brackets when they have been found in wild strains.

[g]Groups formerly called O:13,22(G1) and O:13,23 (G2) were lumped together in a single group O:13.

Genetics Analysis of 16S rRNA gene sequences indicates that salmonellae belong to the *Gammaproteobacteria* (Chang et al., 1997). *S. enterica* and *S. bongori* (Table BXII.γ.261) were further separated by 16S rDNA analysis and found to be closely related to the *E. coli* and *Shigella* complex by both 16S and 23S rDNA analyses (Christensen et al., 1998).

A total of 1160 genes are located on the genetic map of Typhimurium strain LT2: 1081 are on the circular chromosome, 29 on the 90-kb virulence-associated plasmid, and 50 are not yet mapped (see review by Sanderson et al., 1996). The linkage map of serovar Typhimurium was first determined by F-mediated conjugation. Hfr strains may be selected after F plasmid transfer. Conjugative chromosomal transfer may occur from *Salmonella* to *E. coli*, from *E. coli* to *Salmonella*, and from one serovar of *Salmonella* to another. Chromosomal genes responsible for O, Vi, and H antigens can be transferred from one genus to the other (Iino and Lederberg, 1964). Crosses may be used to localize the regions of the bacterial chromosome that specify avirulence for mice (Krishnapillai and Baron, 1964) or to study the role of O antigen factors in the virulence of *Salmonella* (Mäkelä et al., 1973).

The physical map of the chromosome of several *Salmonella* serovars is now available. Comparisons of these maps show that serovar Typhimurium (Liu and Sanderson, 1992; Liu et al., 1993b), serovar Enteritidis (Liu et al., 1993a), serovar Paratyphi B (Liu et al., 1994a), serovar Paratyphi A (Liu and Sanderson, 1995a), and serovar Typhi (Liu and Sanderson, 1995b) share a common basic genomic structure: genome sizes are all between 4600 and 4800 kb, the order of genes on chromosome segments is usually the same, and all have seven *rrn* operons. Relative to other *Salmonella* serovars, the genomic cleavage map of serovar Paratyphi A shows an insertion of about 100 kb between *rrnH-G* and *proB*, and an inversion of half the genome between *rrnH* and *rrnG*. The chromosome of serovar Typhi has undergone major genetic rearrangements (Liu and Sanderson, 1995b), including (1) homologous recombination between the seven *rrn* operons; (2) inversion that covers the replication terminus region; and (3) at least three insertions, one of which is up to 118 kb long and contains the *viaB* locus for Vi antigen biosynthesis.

As with other *Enterobacteriaceae*, salmonellae may harbor "foreign" replicons (such as temperate phages and plasmids) that may code for virulence determinants, for antibiotic resistance, for antigenic changes of O antigen, and for metabolic characteristics commonly used in diagnostic identification, e.g., lactose or sucrose fermentation (Le Minor et al., 1973, 1974). Thus it is unwise to exclude *Salmonella* solely based on a positive lactose or sucrose reaction. It is also more difficult to identify salmonellae when a pleiotrophic mutation occurs, such as one that simultaneously affects nitrate, tetrathionate, and thiosulfate reductase as well as hydrogenlyase (Le Minor, et al., 1969).

About 5% of *Salmonella* strains produce bacteriocins active against *E. coli*, *Shigella*, and/or *Salmonella* (Fredericq, 1948). Most of these bacteriocins adsorb to the same receptor as that for colicins B, E1, E2, or I. *Salmonella* bacteriocins differ from colicins *sensu stricto* by their activity spectra on colicin indicator strains. Some of these *Salmonella* bacteriocins are not even active against colicin indicator strains but are active against *Salmonella* strains only (Hamon and Péron, 1966).

Susceptibility to the O1 phage Most strains of the genus *Salmonella* are susceptible to the O1 phage of Felix and Callow (1943). This phage is highly specific for *Salmonella*, lysing more than 98% of the strains studied in routine *Salmonella* diagnosis (Kallings, 1967). Susceptibility of *Salmonella* species and subspecies to phage O1 is reported in Table BXII.γ.261. Mutations conferring resistance to O1 phage have been studied by Lindberg and Holme (1969), MacPhee et al. (1975), and Hudson et al. (1978).

A *Salmonella* phage that infects only flagellated bacteria was isolated by Sertic and Boulgakov (1936). Sensitivity to this phage depends on the antigenic specificity of the H antigen. For example, bacteria with antigens of the "G" complex are resistant (Meynell, 1961).

Pathogenicity *Salmonella* serovars may be strictly adapted to one particular host (these serovars are auxotrophic), may be ubiquitous (found in a large number of animal species), or may be of still unknown pathogenicity.

Serovars adapted to humans (e.g., serovar Typhi, serovar Paratyphi A, and serovar Sendai) usually cause severe diseases with septicemia-typhoidic syndrome. They are not naturally pathogenic for other animal species. Salmonellosis is transmitted from person to person, without an intermediate host, through fecal contamination of water and food. The incidence is higher in developing countries with poor hygiene. Typhoid fever, a systemic infection caused by serovar Typhi, remains a major public concern. The World Health Organization has estimated that there are more than 16.6 million typhoid cases per year worldwide, causing 600,000 deaths yearly (Ivanoff and Levine, 1997).

Other serovars are adapted to one animal species: serovar Abortusovis is adapted to sheep and is a major cause of abortion in ewes; serovar Typhisuis and serovar Gallinarum are adapted to swine and poultry, respectively.

Ubiquitous *Salmonella* serovars (e.g., serovar Typhimurium) are mainly responsible for food-borne infections. Low infective doses ($<10^3$) are sufficient to cause clinical symptoms (Blaser and Newman, 1982). Salmonellosis of newborns and infants (who are more susceptible to infections than adults) presents diverse clinical symptoms, from a grave typhoid-like illness with septicemia to a mild or asymptomatic infection. In pediatric wards, the infection is usually transmitted by the hands of personnel.

The entrance of a serovar into a food chain may be the origin of its importation into a country. For example, many countries have become infected with serovar Hadar introduced by imported turkeys, or by serovar Enteritidis introduced by imported poultry and eggs.

After recovery from a clinical case of salmonellosis, some patients, although asymptomatic, remain carriers for weeks, months, or years (i.e., continue to eliminate salmonellae in feces). Carriage contributes to the dissemination of salmonellosis, especially if the diagnosis of the carrier state is not monitored by periodic stool cultures. Antibiotics that are active in curing the disease are usually ineffective in the treatment of the carrier state.

Strains of *Salmonella* from urine are often of the R form. Bilharziosis, a parasitic infection caused by *Schistosoma*, has to be controlled in *Salmonella* carriers (Lo Verde et al., 1980). Sickle-cell anemia must be suspected in cases of osteomyelitis due to *Salmonella* in black children (Vandepitte et al., 1953).

The first step in *Salmonella* pathogenicity is the invasion of the small bowel mucosa. Electron microscopic studies showed that *Salmonella* rapidly adhered to and entered M cells of the follicle-associated epithelium and subsequently invaded absorptive enterocytes. This essential feature of *Salmonella* pathogenesis may be conceptualized as a two-step process. Bacteria may adhere to the target cell first, thereupon inducing an endocytic event that results in internalization of *Salmonella*. The intimate interaction between the bacterium and the host cell appears to trigger cytoskeletal rearrangements and membrane ruffling of the epithelial cell, which ultimately leads to bacterial uptake by macropinocytosis. Complexity of the mechanisms governing *Salmonella* entry into epithelial cells is reflected by the large number of loci involved in this process. Most of them are clustered at centisome 63 of the *Salmonella* chromosome (reviewed by Galan, 1996a, 1996b). In the second step of *Salmonella* pathogenesis, bacteria gain access to the mesenteric lymph nodes, drain through the lymphatics to the thoracic duct into the blood, and ultimately infect the liver and spleen. It is now well established that pathogenic serovars of *Salmonella* other than serovar Typhi contain a plasmid that is essential for systemic dissemination in the appropriate host. Although the role of this virulence-associated plasmid is not fully understood, it is currently thought that plasmid products enhance bacterial growth within the reticuloendothelial system of the host (reviewed by Gulig et al., 1993). In human beings, systemic dissemination of serovar Typhi in the reticuloendothelial system requires expression of the Vi antigen. It was shown that the presence of Vi antigen was associated with resistance to the bactericidal effect of serum, resistance to activation of complement by the alternative pathway, resistance to opsonization by inhibition of C3b binding to bacteria, and resistance to post-phagocytic oxidative burst (reviewed by Virlogeux-Payant and Popoff, 1996).

Antibiotic and drug sensitivity Similarly to *E. coli*, *Salmonella* strains can readily acquire plasmids that contain genes conferring resistance to antibiotics. Multiple resistance is selected for when antibiotics are used extensively in hospitals or added to animal feed. The same plasmids may be found in strains of human or animal origin (Anderson et al., 1975). Since around 1990, strains of serovar Typhi have emerged that are resistant to most previously useful oral antibiotics. The antimicrobials that remain effective are relatively expensive (e.g., fluoroquinolones and ceftriaxone) and some must be administered parentally (e.g., ceftriaxone), thereby posing a quandary for developing countries (reviewed by Ivanoff and Levine, 1997). Similarly, multiple antibiotic-resistant strains of serovar Typhimurium definitive type (DT) 104 have emerged recently (Wall et al., 1994; Glynn et al., 1998; Poppe et al., 1998). They are pathogenic for humans and animals, particularly cattle. The DT104 strains were isolated in the United States, Canada, and Europe. More prudent use of antimicrobial agents in farm animals and more effective disease prevention on farms are necessary to reduce the dissemination of this multi-drug-resistant pathogen (Glynn et al., 1998).

Ecology Although some *Salmonella* serovars are strictly host adapted, the majority have a wide host range (e.g., serovar Typhimurium). Some are localized in a particular region of the globe (e.g., serovar Sendai in the Far East, serovar Berta in North America), but others are ubiquitous (e.g., serovar Typhimurium). Strains belonging to *S. enterica* subsp. *salamae*, subsp. *arizonae*, and subsp. *diarizonae* are frequently isolated from the intestinal contents of cold-blooded animals and only rarely from human beings and warm-blooded animals. Strains of subsp. *houtenae* and *S. bongori* are isolated chiefly from the environment and are rarely pathogenic for humans.

Enrichment and Isolation Procedures

Isolation from blood is done according to the classical method for hemoculture. A biphasic culture bottle containing a vertical agar layer along one side and a broth medium at the bottom (Castaneda, 1947; Hall et al., 1979; Krieg and Gerhardt, 1981) prepared with tryptic soy agar/broth containing 2% sodium citrate is convenient. Isolated colonies grow on the agar layer. Identification is usually done by (a) diagnosis of the family *Enterobacteriaceae*, (b) diagnosis of the genus *Salmonella* (diagnosis of the subspecies for strains isolated from blood cultures is not

routinely necessary, because almost all blood isolates belong to subsp. *enterica*), (c) diagnosis of the serovar, (d) determination of the antibiotic susceptibility pattern, and (e) further study of the biovar and phagovar if indicated.

Selective procedures are needed for the isolation of *Salmonella* from specimens containing mixed bacterial flora (fecal samples, autopsy samples, food, environmental samples, etc.). Enrichment (i.e., an increased ratio of *Salmonella* cells to other bacterial cells during incubation) is obtained using liquid nutrient media containing selective agents that inhibit or retard growth of bacteria other than *Salmonella*. Use of enrichment media is essential when the number of salmonellae in a sample is very low, i.e., when the probability of finding colonies by direct isolation is low. Three media may be recommended for general use: (a) the tetrathionate medium of Muller (1923); (b) Muller's medium modified by Kauffmann (1935) by addition of bile and brilliant green; and (c) selenite F broth devised by Leifson (1936). Tetrathionate and selenite broth are suitable for all *Salmonella* serovars. Tetrathionate bile brilliant-green medium is suitable for all serovars, except host-adapted serovars such as serovar Typhi. Enrichment media should be heavily inoculated, e.g., 0.5 ml of fecal suspension per 10 ml of medium. After incubation for 18 h at 37°C, a loopful of enrichment culture is streaked onto agar plating medium.

The same enrichment media may be used for detection of salmonellae in water. The simplest method is to add one volume of the water sample to an equal volume of double-strength medium. For detecting salmonellae in food, a generally suitable procedure is to inoculate 25 g of the suspected food into 225 ml of selenite F broth, incubate for 24 h, and isolate on selective agar media. In the case of a dehydrated food, nutrient broth containing the sample is incubated overnight before inoculation of enrichment media.

Agar media are used for isolation of salmonellae. Streaking a loopful of enrichment culture or a suspension of the sample (e.g., stool) should be done carefully to obtain the greatest number of perfectly isolated colonies. Because the most discriminating character is lactose fermentation, the majority of media for isolation contain lactose and a pH indicator. In addition, the media contain selective agents to inhibit the growth of non-*Salmonella* organisms and the swarming of *Proteus mirabilis* and *P. vulgaris*. Some media also contain ferrous citrate detection of H_2S-producing bacteria.

Examples of media of moderate selectivity are (a) MacConkey agar, which contains lactose, neutral red, and the selective inhibitors crystal violet and bile salts; lactose-positive colonies are red, lactose-negative colonies are colorless; and (b) desoxycholate citrate agar, which contains lactose, neutral red, and the selective agent desoxycholate; ferric ammonium citrate is included as an indicator of H_2S production; lactose-positive colonies are red; lactose-negative colonies are colorless; if H_2S is produced, the inner part of the colony is black.

Examples of media of higher selectivity are the following: (a) Salmonella–Shigella (SS) agar, which contains lactose, neutral red, and the selective agents brilliant green and bile salts. Ferric citrate is an indicator of H_2S production. The appearance of colonies is the same as on desoxycholate citrate agar. (b) Brilliant green agar, which contains lactose, phenol red, and the selective agent brilliant green. This medium is easy to prepare and is suitable for all salmonellae except host-adapted serovars. It is not suitable for shigellae. Lactose-positive colonies are green, lactose-negative colonies are pink. All of the above-mentioned media were reviewed by Kauffmann (1966) and Edwards and Ewing (1972). (c) Hektoen enteric medium (King and Metzger, 1968), which contains lactose, sucrose and salicin, a mixture of bromothymol blue and Andrade's pH indicator, ferric citrate to detect H_2S production, and sodium desoxycholate as a selective inhibitor. Colonies that do not ferment any of the three sugars (e.g., *Salmonella*) are blue-green, with a black center if H_2S is produced. Colonies fermenting one or more of the sugars (e.g., *E. coli*, *Enterobacter cloacae*) are salmon-colored. This medium is suitable for all *Salmonella* serovars and for shigellae.

A general procedure for the detection of salmonellae in feces or food is as follows. A suspension of the sample in saline is streaked onto the chosen isolation medium and also inoculated into an enrichment broth. After overnight incubation, the plating medium is examined for suspect colonies (lactose negative, H_2S positive or negative); also, a loopful of the enrichment culture is streaked onto another plate of selective agar medium. After overnight incubation, this plate is also examined for suspect colonies. A quick screening of several suspect colonies is done by inoculating each into a few drops of urea medium and incubating at 37°C for 2 h. Biochemical characterization is continued only for urease-negative colonies (urease-positive colonies growing at 18 h are likely to be *Proteus*) by inoculating, e.g., triple sugar–iron (TSI) or Kligler-Hajna medium. *Salmonella* must be differentiated mainly from *Citrobacter freundii*, *P. mirabilis*, and, in food bacteriology, *Alteromonas putrefaciens*. To detect *Salmonella* belonging to subsp. *arizonae* and serovar Diarizonae, attention should be given to lactose-positive, H_2S-positive colonies on plating media.

Maintenance Procedures

Salmonella cultures remain viable for many years when stored on peptone agar (meat extract, 5.0 g; peptone, 10.0 g; NaCl, 3.0 g; $Na_2HPO_4 \cdot 12H_2O$, 2.0 g; agar, 10.0 g; distilled water, 1000 ml; pH 7.4) and distributed into small, tightly stoppered, screw-capped tubes. This medium is stab-inoculated and kept in the dark at room temperature. Lyophilization and freezing at or below −70°C give very good results. For lyophilization, it is necessary to isolate each subculture and to select a colony with the desired serologic characteristics.

Differentiation of the genus *Salmonella* from other genera

Characteristics useful for differentiating the genus *Salmonella* from other *Enterobacteriaceae* are given in Tables BXII.γ.193, BXII.γ.194, and BXII.γ.196 of the chapter on the family *Enterobacteriaceae*.

Taxonomic Comments

The species concept in the genus *Salmonella* has evolved in several overlapping phases. The typhoid bacillus was first observed by Eberth (1880) in spleen sections and mesenteric lymph nodes from a patient who died from typhoid fever. During the following decade, other bacteria were isolated from clinical cases of typhoid fever, but they were distinct from the typhoid bacillus both culturally and serologically. The genus *Salmonella* was created by Lignières (1900). Hence, *Salmonella* strains were considered different species when isolated from different conditions or different hosts. However, it was soon realized that a number of these so-called species were ubiquitous, and emphasis shifted to antigenic properties.

Serological analysis of *Salmonella* O and H antigens was initiated by White (1926). This work was extended by Kauffmann (1961), who defined species as "a group of related sero-fermentative phage types". Consequently, each *Salmonella* serovar was considered as a species. But, as most serovars could not be distinguished by biochemical tests, Kauffmann (1966) divided the

genus *Salmonella* into four subgenera (I–IV) and continued to apply his concept of "one serovar–one species". Nevertheless, phenotypic studies and numerical taxonomy showed that, apart from host-adapted serovars, *Salmonella* serovars within each subgenus were biochemically indistinguishable (reviewed by Le Minor and Popoff, 1987). For this reason, Kauffmann's subgenera were considered to be species (Le Minor et al., 1970b).

Later, DNA relatedness studies demonstrated that all *Salmonella* serovars formed a single DNA hybridization group with seven subgroups delineated by studies of the thermal stability of hybrids (Crosa et al., 1973a; Stoleru et al., 1976; Le Minor et al., 1986). The seven DNA subgroups could be differentiated by using biochemical characteristics. Correlation between DNA subgroups and Kauffmann's subgenera was close except that subgenus III was split into two DNA subgroups containing monophasic and diphasic serovars, respectively.

Based on these numerical taxonomy and DNA relatedness studies, it was proposed that the genus *Salmonella* should consist of a single species that could be divided into seven subspecies (I–VII), although subspecies V might possibly represent a second species (Le Minor et al., 1982, 1986). The strict application of the Bacteriological Code (Rules Revision Committee, Judicial Commission, International Committee on Systematic Bacteriology, 1985) led Le Minor et al. (1982, 1986) to propose *S. choleraesuis* as the species name, having seven subspecies designated subsp. *choleraesuis*, subsp. *salamae*, subsp. *arizonae*, subsp. *diarizonae*, subsp. *houtenae*, subsp. *bongori*, and subsp. *indica*. Subspecies names were validated by announcement in the *International Journal of Systematic Bacteriology* (1985, 1987). However, the name *S. choleraesuis* could be considered as an ambiguous name since this name was used for the serovar possessing the antigenic formula 6,7:c:1,5 (Table BXII.γ.262). To avoid further confusion, it was proposed that the type species of the genus *Salmonella* be *S. enterica* (Le Minor and Popoff, 1987). This name, first proposed by Kauffmann and Edwards (1952), received unanimous support from the members of the Subcommittee of *Enterobacteriaceae* of the International Committee on Systematic Bacteriology at the XIV International Congress of Microbiology (Manchester, U.K., 1986). However, the request to change the name of the type species to *S. enterica* was not approved by the Judicial Commission. A second request has been made and, in the interim, the WHO collaborating center for reference and research on *Salmonella* and national *Salmonella* reference laboratories are using *S. enterica*.

Finally, by using multilocus enzyme analysis, it was shown that *S. enterica* subsp. *bongori* had evolved considerably from other subspecies (Reeves et al., 1989a). Based on this divergence and on DNA relatedness data (Le Minor et al., 1982; 1986), Reeves et al. (1989a) proposed that *S. enterica* subsp. *bongori* be elevated to the level of species in the new combination *S. bongori*.

The practice of giving names to the serovars of *S. enterica* subsp. *enterica* should continue since the diagnostic use of the Kauffmann–White scheme (Table BXII.γ.262) is overridingly important and since these names are very familiar to microbiologists and physicians. However, these names must no longer be italicized and the first letter must be a capital. Serovars of the other subspecies of *S. enterica* and those of *S. bongori* should be designated only by their antigenic formulae.

Differentiation of the species of the genus *Salmonella*

Table BXII.γ.261 presents the biochemical characteristics differentiating the species and subspecies of the genus *Salmonella*. The antigenic formulae of *Salmonella* serovars (i.e., the Kauffmann–White scheme) is given in Table BXII.γ.262. An alphabetical listing of serovars indicating the O groups is presented in Table BXII.γ.263.

List of species of the genus Salmonella

1. **Salmonella enterica** (ex Kauffmann and Edwards 1952) Le Minor and Popoff 1987, 466.
en.te.ri'ca. Gr. n. *enteron* gut; L. adj. *enterica* of the gut.

The description of *S. enterica* is that of *S. choleraesuis sensu* (Le Minor et al., 1982). The characteristics are as described for the genus (see Tables BXII.γ.193, BXII.γ.194, and BXII.γ.196 of the chapter on the family *Enterobacteriaceae* and as listed in Table BXII.γ.261. *S. enterica* can be divided into six subspecies (Le Minor et al., 1982, 1986; Reeves et al. 1989a).

The type strain carries a virulence-associated plasmid of about 90 kb. Antigenic formula 4,5,12:i:1,2 (serovar Typhimurium).

The mol% G + C of the DNA is: 50–53 (hydrolysis and chromatography, Bd, T_m).

Type strain: LT2, ATCC 43971, CIP 60.62, NCIB 11450.

a. **Salmonella enterica** *subsp.* **enterica** (ex Kauffmann and Edwards 1952) Le Minor and Popoff 1987, 467.

Distinguished from other *S. enterica* subspecies by the characteristics reported in Table BXII.γ.261. Contains at least 1443 serovars (Popoff et al., 1998). Isolated mainly from humans and warm-blooded animals.

A list of selected serovars belonging to *S. enterica* subsp. *enterica* is given below.

The mol% G + C of the DNA is: see species description.

Type strain: LT2, ATCC 43971, CIP 60.62, NCIB 11450.

i. **Salmonella enterica** *subsp.* **enterica** *serovar* **Choleraesuis** (Smith 1894) Weldin 1927, 155 (*Bacillus cholerae suis* Smith 1894, 9.)
chol.er.ae.su'is. Gr. n. *cholera* cholera; L. n. *sus* hog. M.L. gen. n. *suis* of a hog; M.L. gen. n. *choleraesuis* of hog cholera.

Antigenic formula: 6,7:c:1,5. The detailed O antigen formula is normally 6_2,7, but this may be transformed by lysogenization into 6_1,7 or 6_2,7,14. Arabinose and trehalose are not fermented; dulcitol is slowly and irregularly fermented. Those strains that produce H_2S are designated as serovar Choleraesuis biovar Kunzendorf. Pathogenic for humans and animals.

The mol% G + C of the DNA is: see species description.

Deposited strain: ATCC 13312, NCTC 5735.

ii. **Salmonella enterica** *subsp.* **enterica** *serovar* **Enteritidis** (Gaertner 1888) Castellani and Chalmers 1919, 939 (*Bacterium enteritidis* Gaertner 1888, 573.)
en.te.ri'ti.dis. Gr. n. *enteron* gut, intestine; M.L. n. *enteritis* enteritis, inflammation of the intestine; M.L. gen. n. *enteritidis* of enteritis.

Antigenic formula: 1,9,12:g,m:−. The presence of factor O1 is connected with lysogenization. Ubiquitous and frequently the cause of infections in humans and

TABLE BXII.γ.263. Alphabetical list of names of *Salmonella* serovars, indicating the O groups

animals; since the last decade, very frequent agent of *Salmonella* gastroenteritis in humans.

The mol% G + C of the DNA is: see species description.

Deposited strain: ATCC 13076.

iii. **Salmonella enterica** *subsp.* **enterica** *serovar* **Gallinarum** (Klein 1889) Bergey, Harrison, Breed, Hammer and Huntoon 1925, 236 (*Bacillus gallinarum* Klein 1889, 689; *Bacterium pullorum* Rettger 1909, 123; *Salmonella gallinarum-pullorum* Taylor, Bensted, Boyd, Carpenter, Dowson, Lovell, Taylor, Thornton, Wilson and Shaw 1952, 140.)
gal.li.na′ rum. L. n. *gallina* hen; L. gen. pl. n. *gallinarum* of hens.

Antigenic formula: 1,9,12:−:−. The presence of factor O1 is connected with lysogenization. Always nonmotile. May be subdivided into biovars based on fermentation characteristics, production of gas, and production of H_2S. Does not grow on a minimal defined medium. Isolated chiefly from chickens and other birds. Causative agent of fowl typhoid.

The mol% G + C of the DNA is: see species description.

iv. **Salmonella enterica** *subsp.* **enterica** *serovar* **Paratyphi A** (Brion and Kayser 1902) Castellani and Chalmers 1919, 939 (*Bacterium paratyphi* Kayser 1902, 426; *Bacterium paratyphi* typhus A Brion and Kayser 1902, 613.)
pa.ra.ty′ phi. Gr. prep. *para* alongside of; Gr. n. *typhus* a stupor; M.L. gen. n. *paratyphi A* of type A typhoid-like infection.

Antigenic formula: 1,2,12:a:−. The presence of factor O1 is connected with lysogenization. Aerogenic. Ferments arabinose but no xylose. The majority of strains do not produce H_2S, and in this respect serovar Paratyphi A is unlike most other salmonellae. Lysine decarboxylase reaction is weak or negative. Pathogenic only for humans.

The mol% G + C of the DNA is: see species description.

v. **Salmonella enterica** *subsp.* **enterica** *serovar* **Paratyphi B** (Brion and Kayser 1902) Bergey, Harrison, Breed, Hammer and Huntoon 1923, 213 (*Bacterium paratyphi* typhus B Brion and Kayser 1902, 613; *Bacillus schottmuelleri* Winslow, Kligler and Rothberg 1919, 479.)
pa.ra.ty′ phi. Gr. prep. *para* alongside of; Gr. n. *typhus* a stupor; M.L. gen. n. *paratyphi B* of type B typhoid-like infection.

Antigenic formula; 1,4,[5],12:b:1,2. The presence of factor O1 is connected with lysogenization. Produces a slime layer when grown on a medium containing 0.5% glucose and 0.2 M sodium phosphate, pH 7. Negative for D-tartrate. Causes enteric fever in humans and very rarely infects animals. A variant known as biovar Java is positive for D-tartrate, fails to produce a slime layer, and usually causes enteritis in humans and not uncommonly in animals as well (Kauffmann, 1941). Some strains are intermediate between these two extremes.

The mol% G + C of the DNA is: see species description.

vi. **Salmonella enterica** *subsp.* **enterica** *serovar* **Paratyphi C** Hirschfeld 1919, 296 (Paratyphoid C bacillus Hirschfeld 1919, 296; *Salmonella hirschfeldii* Weldin 1927, 161; *Salmonella* paratyphi-C International Salmonella Subcommittee 1934.)
pa.ra.ty′ phi. Gr. prep. *para* alongside of; Gr. n. *typhus* a stupor; M.L. gen. n. *paratyphi C* of type C typhoid-like infection.

Antigenic formula; 6,7,[Vi]:c:1,5. Ferments dulcitol and trehalose; produces H_2S. Arabinose fermentation is variable.

The mol% G + C of the DNA is: see species description.

vii. **Salmonella enterica** *subsp.* **enterica** *serovar* **Typhi** (Schroeter 1886) Warren and Scott 1930, 416 (*Bacillus typhi* Schroeter 1886, 165.)
ty′ phi. Gr. n. *typhus* a stupor; M.L. gen. n. *typhi* of typhoid.

Antigenic formula: 9,12,[Vi]:d:−. Wild strains may possess H antigen z66 instead of H antigen d (Guinée et al., 1981). Does not grow on Simmons' citrate medium or on a minimal defined medium; requires at least tryptophan as a growth factor. Does not produce gas from glucose or other sugars. Fermentation of xylose is variable. Many strains are agglutinated by anti-Vi serum and are inagglutinable by anti-09 serum; their colonies (V colonies) are opaque and have an iridescent appearance when examined by transmitted light. Colonies of intermediate appearance agglutinable by both Vi and O antisera may occur (VW colonies). Pathogenic only for humans, causing typhoid (enteric) fever; transmitted by water or food contaminated by human excreta.

The mol% G + C of the DNA is: see species description.

Deposited strain: ATCC 19430.

viii. **Salmonella enterica** *subsp.* **enterica** *serovar* **Typhimurium** (Loeffler 1892) Castellani and Chalmers 1919, 939 (*Bacterium typhimurium* Loeffler 1892, 134.)
ty.phi.mu′ ri.um. Gr. n. *typhus* a stupor; L. n. *mus* mouse; L. gen. pl. n. *murium* of mice; M.L. gen. pl. n. *typhimurium* typhoid of mice.

Antigenic formula: 1,4,[5],12:i:1,2. The presence of factor O1 follows lysogenization by a converting phage named *iota* or PLT22. Ubiquitous and frequently the cause of infections in humans and animals; very frequent agent of *Salmonella* gastroenteritis in man.

The mol% G + C of the DNA is: see species description.

Deposited strain: ATCC 13311.

b. **Salmonella enterica** *subsp.* **arizonae** (Borman 1957) Le Minor and Popoff 1987, 467 (*Salmonella choleraesuis* subsp. *arizonae* (Borman 1957) Le Minor, Véron and Popoff 1985, 375; *Salmonella arizonae* (Borman 1957) Kauffmann *in* van Oye 1964; *Paracolobactrum arizonae* Borman 1957, 347.)
a.ri.zo' nae. M.L. gen. n. *arizonae* of Arizona, a state in the United States.

Distinguished from other *S. enterica* subspecies by the characteristics reported in Table BXII.γ.261. Contains at least 94 serovars (Popoff et al., 1998). All serovars belonging to this subspecies are monophasic for the H antigen. Isolated mainly from cold-blooded animals and environment.

Antigenic formula: 51:z_4,z_{23}:−.
The mol% G + C of the DNA is: see species description.
Type strain: ATCC 13314, CIP 82.30, NCTC 8297.

c. **Salmonella enterica** *subsp.* **diarizonae** (Le Minor, Véron and Popoff 1985) Le Minor and Popoff 1987, 467 (*Salmonella choleraesuis* subsp. *diarizonae* Le Minor, Véron and Popoff 1985, 375.)
di.a.ri.zo' nae. Gr. adj. *dis* twice, two; M.L. gen. n. *arizonae* of Arizona, a state in the United States.

Distinguished from other *S. enterica* subspecies by the characteristics reported in Table BXII.γ.261. Contains at least 323 serovars (Popoff et al., 1998). All serovars belonging to this subspecies are diphasic for the H antigen. Isolated mainly from cold-blooded animals and environment.

Antigenic formula: 6,7:l,v:z_{53}.
The mol% G + C of the DNA is: see species description.
Type strain: ATCC 43973, CIP 82.31, NCTC 10060.

d. **Salmonella enterica** *subsp.* **houtenae** (Kauffmann 1962) Le Minor and Popoff 1987, 467 (*Salmonella choleraesuis* subsp. *houtenae* (Kauffmann 1962) Le Minor, Rohde and Taylor 1970b, 209; *Salmonella houtenae* Kauffmann 1962, 353.)
hou' te.nae. M.L. gen. n. *houtenae* of Houten, a town in Holland.

Distinguished from other *S. enterica* subspecies by the characteristics reported in Table BXII.γ.261. Contains at least 70 serovars (Popoff et al., 1998). All serovars belonging to this subspecies are monophasic for the H antigen. Isolated mainly from cold-blooded animals and environment.

Antigenic formula: 41:g,z_{51}:−.
The mol% G + C of the DNA is: see species description.
Type strain: ATCC 43974, CIP 82.32, NCTC 10401.

e. **Salmonella enterica** *subsp.* **indica** (Le Minor, Popoff, Laurent and Hermant 1987) Le Minor and Popoff 1987, 467 (*Salmonella choleraesuis* subsp. *indica* Le Minor, Popoff, Laurent and Hermant 1987, 179.)
in.di' ca. L. adj. *indica* of India.

Distinguished from other *S. enterica* subspecies by the characteristics reported in Table BXII.γ.261. Contains at least 11 serovars (Popoff et al., 1998). Isolated mainly from cold-blooded animals and environment.

Antigenic formula: 1,6,14,25:a:e,n,x.
The mol% G + C of the DNA is: see species description.
Type strain: ATCC 43976, CIP 102501.

f. **Salmonella enterica** *subsp.* **salamae** (Le Minor, Rohde and Taylor 1970b) Le Minor and Popoff 1987, 467 (*Salmonella choleraesuis* subsp. *salamae* (Le Minor, Rohde and Taylor 1970b) Le Minor, Véron and Popoff 1985, 375) (*"Salmonella salamae"* Le Minor, Rohde and Taylor 1970b, 209.)
sa.la' mae. M.L. gen. n. *salamae* of (Dare-es) salaam.

Distinguished from other *S. enterica* subspecies by the characteristics reported in Table BXII.γ.261. Contains at least 488 serovars (Popoff et al., 1998). Isolated mainly from cold-blooded animals and environment.

Antigenic formula: 1,9,12:l,w:e,n,x.
The mol% G + C of the DNA is: see species description.
Type strain: ATCC 43972, CIP 82.29, NCTC 5773.

2. **Salmonella bongori** (Le Minor, Véron and Popoff 1985); Reeves, Evins, Heiba, Plikaytis and Farmer 1989b, 371[VP] (Effective publication: Reeves, Evins, Heiba, Plikaytis and Farmer 1989a, 319) (*Salmonella choleraesuis* subsp. *bongori* Le Minor, Véron and Popoff 1985, 375.)
bon' gori. M.L. gen. n. *bongori* of Bongor, a town in Chad.

The characteristics are as described for the genus (see also Table BXII.γ.193 in the chapter on the family *Enterobacteriaceae*) and as listed in Table BXII.γ.261. All serovars belonging to *S. bongori* are monophasic for the H antigen. Contains at least 20 serovars (Popoff et al., 1998). Isolated mainly from cold-blooded animals and environment.

Antigenic formula: 66:z_{41}:−.
The mol% G + C of the DNA is: 51.8 ± 0.6 (T_m).
Type strain: ATCC 43975, CIP 82.33.
GenBank accession number (16S rRNA): AF029227.

Genus XXXIV. **Serratia** *Bizio 1823, 288*[AL]

Francine Grimont and Patrick A.D. Grimont

Ser.ra' ti.a. M.L. fem. n. *Serratia* named after Serafino Serrati, an Italian physicist.

Straight rods, 0.5–0.8 × 0.9–2.0 µm in length, with rounded ends. Conform to the general definition of the family *Enterobacteriaceae*. Gram negative, generally **motile**, by means of peritrichous flagella. **Facultatively anaerobic. Nitrate and chlorate are reduced anaerobically. Growth factors are generally not required.** Colonies on nutrient agar are most often opaque, somewhat iridescent, and either **white, pink, or red in color**. Almost all strains can grow at temperatures between 10 and 36°C, at pH 5–9, and in the presence of 0–4% (w/v) NaCl. The catalase reaction is strongly positive. **D-Glucose is fermented** through the Embden–Meyerhof pathway. The major glucose entry route involves a phosphoenolpyruvate-dependent phosphotransferase system with both enzyme II^{Glc} (glucose permease) and enzyme II^{Man} (mannose permease). Glucose is also oxidized to gluconate in the presence of pyrroloquinoline quinone. **Gluconate is oxidized to 2-ketogluconate. Acetoin is produced from pyruvate** by all species except *S. fonticola*. Fructose, D-galactose, maltose, D-mannitol, D-mannose, ribose, and trehalose are fermented and utilized as sole carbon sources. L-fucose is fermented and utilized as sole carbon source by all species except *S. fonticola*. L-sorbose

is not fermented or utilized as sole carbon source. All species but *S. fonticola* fail to ferment or utilize dulcitol and tagatose. *N*-acetylglucosamine, D-alanine, L-alanine, citrate, D-galacturonate, D-glucosamine, D-glucuronate, 2-ketogluconate, L-proline, putrescine, L-serine are utilized as sole carbon sources by most strains. Caprate, caproate, **caprylate**, and tyrosine are **utilized** as sole carbon sources by all species except *S. fonticola*. 5-Aminovalerate, butyrate, *m*-coumarate, ethanolamine and tryptamine are not utilized as sole carbon sources. All species except *S. fonticola* fail to utilize 3-phenylpropionate. All species except *S. entomophila* fail to utilize itaconate. Phenylalanine, histidine, and tryptophan deaminases and thiosulfate reductase (H_2S from thiosulfate) are not produced. ***o*-Nitrophenyl-β-D-galactopyranoside** (ONPG) is **hydrolyzed by most strains**. Esculin is hydrolyzed by most strains except *S. proteamaculans* subsp. *quinovora*. **Extracellular enzymes** of all species except *S. fonticola* **hydrolyze DNA, lipids** (tributyrin, corn oil) **and proteins** (gelatin, casein), but not starch (in four days), polygalacturonic acid, or pectin. Tween-80 is hydrolyzed by all species except *S. odorifera*. The organisms **occur in the natural environment** (soil, water, plant surfaces) or **as opportunistic human pathogens**.

The mol% G + C of the DNA is: 52–60.

Type species: **Serratia marcescens** Bizio 1823, 288.

Further descriptive information

Phylogenetic affinities among *Serratia* species have been studied (Fig. BXII.γ.208) (Dauga et al., 1990; Spröer et al., 1999). Three clusters can be observed in all studies: cluster I includes *S. marcescens* and *S. rubidaea*, cluster II includes psychrotrophic species (*S. proteamaculans*, *S. grimesii*, *S. liquefaciens*, *S. plymuthica*, and *S. fonticola*), and cluster III includes *S. ficaria* and *S. entomophila*. Depending on the analysis, *S. odorifera* may branch with cluster I or after clusters II and III have merged. Sequence comparisons leave no doubt as to the affiliation of *S. fonticola* to the genus *Serratia* and especially to the psychrophilic group of species.

Cells of *Serratia* rarely show a visible capsule in India ink mounts, although mucoid colonies can be observed in *S. plymuthica* and occasionally in other *Serratia* species; however, cells of *S. odorifera* possess a microcapsule which can be evidenced by the quellung reaction (capsular swelling) using *Klebsiella* anticapsule K4 or K68 sera (Richard, 1979). Polysaccharides excreted by cells of *S. marcescens* can be extracted from the cell surface layer or from the culture medium. These polysaccharides contain chiefly D-glucose and glucuronic acid and lower proportions of

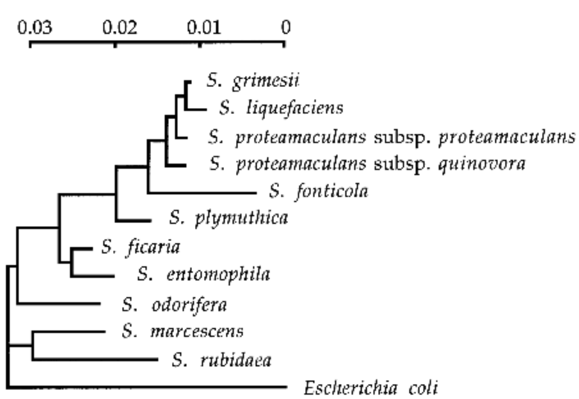

FIGURE BXII.γ.208. Phylogenetic tree of the genus *Serratia*. The tree was built by the neighbor-joining method (Saitou and Nei, 1987). Scale is in K_{nuc} according to Jukes and Cantor (1969).

D-mannose, heptose, L-fucose and L-rhamnose (Adams and Martin, 1964; Adams and Young, 1965).

The major fatty acid components found in whole-cell methanolysates are $C_{14:0\ 3OH}$, $C_{16:0}$, $C_{16:1}$, $C_{18:1}$, and $C_{18:2}$, contributing 50–80% of the components in each strain. $C_{14:0}$ contributes 3.7–9.4% whereas other components contribute less than 3% each (Bergan et al., 1983).

Colony diameters are ~1.5–2.0 mm after overnight growth on nutrient agar. Swarming does not occur.

Two different pigments can be produced by various *Serratia* strains: prodigiosin and pyrimine (Williams and Qadri, 1980). Prodigiosin, a nondiffusible, water-insoluble, red pigment bound to the cell envelope, is produced by two biogroups (A1 and A2) of *S. marcescens* and by most strains of *S. plymuthica* and *S. rubidaea*. Prodigiosin-producing colonies are totally red or show either a red center, a red margin, or red sectors. The exact color given by the pigment depends upon cultural conditions (e.g., amino acids, carbohydrates, pH, inorganic ions, temperature) and may include orange, pink, red, or magenta. Prodigiosin is best produced on peptone-glycerol agar at 20–35°C. The temperature range for pigment production is 12–36°C. Prodigiosin is not produced anaerobically. Chemically, prodigiosin is a tripyrrole derivative, 2-methyl-3-amyl-6-methoxyprodigiosene (prodigiosene is 5-(2-pyrryl)-2,2′-dipyrrylmethene). In the cell, prodigiosin is formed by condensation of a volatile 2-methyl-3-amylpyrrol (MAP) and a nonvolatile 4-methoxy-2-2′-bipyrrole-5-carboxaldehyde (MBC). Several classes of nonpigmented mutants that are blocked on either the MAP pathway or the MBC pathway have been isolated. Syntrophic pigmentation may occur when two different class mutants are grown side by side (Williams and Qadri, 1980).

Pyrimine, a water-soluble, diffusible pink pigment (Williams and Qadri, 1980), is produced by some strains of *S. marcescens* biogroup A4. Ferrous iron is required for the production of pyrimine. Pyrimine is L-2(2-pyridyl)-D′-pyrroline-5-carboxylic acid. When pyrimine is produced, the agar medium turns pink while the colonies are white to pinkish.

A yellow diffusible pigment, 2-hydroxy-5-carboxymethylmuconic acid semialdehyde, is produced from the meta cleavage of 3,4-dihydroxyphenylacetic acid (3,4-DHP) by the enzyme 3,4-DHP 2,3-dioxygenase (Trias et al., 1988), induced by tyrosine in all *S. marcescens* strains. At present, only *S. marcescens* strains of biotype A8a which have lost the ability to grow on aromatic compounds can produce the yellow pigment. A new reddish violet pigment, a peptide-ferropyrimine complex, produced by a *S. marcescens* O5:H1 was described by Suzuki et al. (1993b).

Cultures can produce two kinds of odors, a fishy to urinary odor attributed to trimethylamine (mixed with some NH_3), or a musty, potato-like odor attributed to alkyl-methoxypyrazine. The musty odor produced by *S. odorifera*, *S. ficaria*, and a few strains of *S. rubidaea* is due to 3-isopropyl-2-methoxy-5-methylpyrasine (Gallois and Grimont, 1985). All other strains and species produce the fishy-urinary odor.

All species except *S. marcescens* and *S. rubidaea* can grow readily at 4–5°C and several grow at 40°C (*S. marcescens* and several strains of *S. rubidaea* and *S. odorifera*); however, the temperature of 37°C is not favorable for the isolation of *S. plymuthica*. When *S. liquefaciens* and *S. plymuthica* are studied, many tests that are positive at 28–35°C give negative results at 37°C (e.g., Voges–Proskauer, decarboxylases, tetrathionate reductase tests).

A strong catalase activity, which can be evidenced with 3% (or

less) H_2O_2, is produced by *Serratia* strains (Taylor and Achanzar, 1972).

There is no sodium ion requirement for growth in the genus *Serratia*; however, the optimum concentration of NaCl for growth is ~0.5% (w/v) for *S. marcescens* or 1% (w/v) for *S. rubidaea* (Grimont and Grimont, unpublished results). Tolerance to NaCl ranges from 5 to 6% (w/v) for *S. plymuthica*, to 10% (w/v) for *S. rubidaea*.

In Biotype-100 strips (BioMerieux, Craponne, France) or a minimal medium containing ammonium sulfate as the nitrogen source, the following compounds serve universally as sole carbon sources for all *Serratia* strains: *N*-acetylglucosamine, *cis*-aconitate, citrate, D-fructose, D-galactose, D-galacturonate, D-gluconate, D-glucosamine, D-glucose, *myo*-inositol, 2-ketogluconate, maltose, maltotriose, D-mannitol, D-mannose, D-ribose, and D-trehalose. Most strains of all species can utilize D-alanine, L-alanine, D-glucuronate, glycerate, glycerol, lactate, putrescine, L-serine, and L-tryptophan. All species except some or all strains of *S. fonticola* can utilize L-aspartate, L-fucose, fumarate, L-glutamate, L-malate, L-proline, and succinate. Utilization of caprate, caproate, and caprylate by all species except *S. fonticola* is better observed in a minimal agar containing ammonium sulfate as the nitrogen source, rather than in Biotype-100 strips. The following compounds are never utilized as sole carbon sources (Biotype-100 strips): DL-5-aminovalerate, *m*-coumarate, ethanolamine, glutarate, sorbose, and tryptamine. The following carbon sources are never utilized by *Serratia* species except some or all *S. fonticola* strains: dulcitol, 3-phenylpropionate, and tagatose (Grimont et al., 1977b, 1978b, 1979b; Grimont and Grimont, 1978b).

Characteristic extracellular enzymes are produced by most species. All species except *S. fonticola* can hydrolyze DNA, gelatin, soluble casein, tributyrin, and corn oil. Only rare strains fail to produce one or more of these extracellular enzymes. All species, except *S. odorifera*, can hydrolyze Tween 80. Chitin is hydrolyzed by all species except *S. rubidaea*, *S. odorifera*, and *S. fonticola*. Lecithin is also hydrolyzed by many strains. Spot-inoculated starch agar (Starch agar: nutrient agar containing 0.5% [w/v] soluble starch), incubated for four days and then flooded with Lugol's iodine, shows no zone of clearing (Grimont et al., 1977b); however, longer incubation (6–14 days) may allow detection of some amylase-producing strains (M. Popoff, personal communication).

A red-pigmented *S. marcescens* has been found to produce a carboxymethyl cellulase (Thayer, 1978). Depolymerization of a carboxymethylcellulose gel is faster with *S. marcescens*, *S. rubidaea*, and *S. liquefaciens* than with *S. odorifera*, *S. ficaria*, and *S. plymuthica* (unpublished results).

Up to 11 proteinases have been revealed by agar gel electrophoresis. Each strain produces one to four different proteinases. Different species have different proteinase patterns (Grimont et al., 1977a). These have been used to type strains (Grimont and Grimont, 1978c). Isoelectric points of the 11 proteinases are between pH 3.6 and pH 6.0 (Grimont and Grimont, 1978b).

Fructose, maltose, D-mannitol, D-mannose, ribose, and trehalose are fermented by all strains. Most strains ferment glycerol and *myo*-inositol. Fermentation of D-glucose is not prevented by 0.001 M iodoacetate (Grimont et al., 1977b, 1978b, 1979b; Grimont and Grimont, 1978b), an inhibitor of the Embden–Meyerhof–Parnas glycolytic pathway and other enzymic reactions. *Serratia* species can produce gluconate-6-phosphate dehydrase and 2-keto-3-deoxygluconate-6-phosphate aldolase (Kersters and De Ley, 1968), which are the characteristic enzymes of the Entner–Doudoroff pathway.

Under aerobic conditions, gluconate is produced from D-glucose in the presence of iodoacetate by all *Serratia* species due to a glucose dehydrogenase, when pyrroloquinoline quinone (PQQ) is added. Only *S. marcescens*, *S. odorifera*, *S. rubidaea*, *S. entomophila*, *S. ficaria*, and some strains of *S. plymuthica* can produce gluconate without added PQQ (Bouvet et al., 1989).

A reducing compound, 2-ketogluconate, is also produced from gluconate by all species due to a gluconate dehydrogenase (Grimont et al., 1977b, 1978a, 1979b; Bouvet et al., 1989).

2,5-Diketogluconate is produced from 2-ketogluconate at 20°C (not at 30°C) due to a 2-ketogluconate dehydrogenase by *S. marcescens*, *S. liquefaciens*, and *S. grimesii* (Bouvet et al., 1989).

In anaerobic glycerol dissimilation, a glycerol dehydrogenase induced by glycerol and not by hydroxyacetone is present in *S. marcescens*, *S. proteamaculans*, *S. liquefaciens*, *S. grimesii*, and *S. fonticola*, but not in *S. rubidaea*, *S. ficaria*, *S. odorifera*, *S. entomophila*, and *S. plymuthica* (Bouvet et al., 1995a). The Voges–Proskauer (VP) test, when done on a 3-day-old culture in Clark–Lubs medium, is negative for 40% of strains of *S. plymuthica*, although acetoin can be detected after incubation for 18 h by use of a sensitive method (Richard, 1972). These strains, which are VP-negative after 3 days of incubation, can utilize 2,3-butanediol as a sole carbon source (Grimont et al., 1978b). *Serratia* strains, other than *S. fonticola*, that cannot produce acetoin from pyruvate (under any experimental conditions) are very rare. *S. fonticola* is always negative for acetoin. A tiny gas bubble is commonly produced by *S. marcescens* in a peptone–water–glucose medium with Durham tube. *S. plymuthica* and *S. liquefaciens* produce a large amount of gas. The end products of glucose fermentation by *S. marcescens* are 2,3-butanediol, ethanol, formate, lactate, succinate, and CO_2 with small amounts of acetate, acetoin, and glycerol and very little or no H_2 (Neish et al., 1948; White and Starr, 1971). The end products yielded by *S. plymuthica* are 2,3-butanediol, ethanol, lactate, succinate, CO_2, H_2, and small amounts of formate, acetate, acetoin, and glycerol (Neish et al., 1948). The 2,3-butanediol produced by *S. marcescens* is mostly a *meso*-isomer, whereas *S. plymuthica* is unique in producing a levo-rotatory 2,3-butanediol (Neish et al., 1948).

Transduction systems in *S. marcescens* have been described (Kaplan and Brendel, 1969; Matsumoto et al., 1973). The earliest genetic transfer described in *S. marcescens* (Belser and Bunting, 1956) is also suggestive of a transduction mechanism. *S. marcescens* was transformed with plasmid pBR322 by Reid et al. (1982). Transformants were selected based on resistance to high levels of ampicillin.

All species of the genus *Serratia* have been delineated by DNA–DNA hybridization. All species of the genus except *S. fonticola* share a number of phenotypic properties. *S. fonticola* was included in the genus *Serratia* because of significant DNA relatedness with other *Serratia* species (Steigerwalt et al., 1976; Gavini et al., 1979); this inclusion was confirmed by comparison of 16S rDNA gene sequences (Dauga et al., 1990). A summary of DNA relatedness within the genus *Serratia* is given in Table BXII.γ.264.

Lactose plasmids have been demonstrated in *S. liquefaciens* (Le Minor et al., 1974) and in *S. marcescens* (C. Coynault, personal communication). Antibiotic resistance plasmids of incompatibility groups S (= H_2), C, L/M, P, W, and FII have been identified in *S. marcescens*. Plasmids of groups M and N have been found in *S. liquefaciens* (Hedges, 1980). Replicon typing, using cloned DNA probes, identified plasmid groups FIB, FIC, FIIA, H12, L/M, N, B/O, P, W, Y, and Com9 in multiresistant *S. marcescens* strains (Llanes et al., 1994).

TABLE BXII.γ.264. DNA relatedness among *Serratia* species[a,b]

Species	Source of labeled DNA: *S. marcescens*[c]	*S. entomophila*	*S. fonticola*	*S. ficaria*[d]	*S. grimesii*	*S. liquefaciens*	*S. odorifera*[c]	*S. plymuthica*	*S. proteamaculans* subsp. *proteamaculans*	*S. proteamaculans* subsp. *quinovora*	*S. rubidaea*
S. marcescens	**92 ± 5.5 d = 0–3.2**	42±6.3 d = 7.5–8.0	50 ± 5.1	46 ± 4.7 d = 8.5–9.5	36	29	31 ± 2.8 d = 10.5–11.5	29	34	33	26 ± 2.1
S. entomophila	ND	**84 ± 8.2 d = 0–1.0**	ND	62 ± 5.4 d = 6.0–9.0	ND	ND	ND	ND	ND	ND	ND

[a]All DNA relatedness values obtained with the S1 nuclease method except otherwise stated. Divergence (d) given rounded to the nearest 0.5.

[b]Data from Steigerwalt et al. (1976), Grimont et al. (1978a, 1979b, 1982b, 1988), and Gavini et al. (1979). Data in the *S. rubidaea* column are unpublished.

[c]DNA relatedness values obtained with the hydroxyapatite method.

[d]DNA relatedness values obtained with the filter method.

Bacteriophages active on *Serratia* are easily found in river water or sewage. Phages that are active on one species of *Serratia* are usually active on strains of other species of that genus, but rarely on strains of other genera (Grimont and Grimont, 1978b). Lysogeny is very common in *Serratia* species (Prinsloo, 1966). Several phage typing systems have been studied (Pillich et al., 1964; Hamilton and Brown, 1972; Farmer, 1974; Grimont, 1977a).

Bacteriocins produced by *Serratia* are of two kinds: (a) a trypsin-resistant, acid-sensitive (pH 2) structure (Hamon and Péron, 1961) called "group A bacteriocin" by Prinsloo (1966) and later found by electron microscopy to resemble phage tails (Traub, 1972); and (b) a trypsin-sensitive, acid-resistant protein (Hamon and Péron, 1961) called "group B bacteriocin" by Prinsloo (1966). Bacteriocins produced by one species of *Serratia* frequently cross-react with other species of this same genus. *Serratia* bacteriocins are also frequently active on *Escherichia coli* K12. *S. marcescens* strains produce group A and/or group B bacteriocins. *S. rubidaea* strains produce only group A bacteriocins. *S. liquefaciens* and *S. ficaria* produce only group B bacteriocins. *S. odorifera* produces neither group A nor group B bacteriocins (Hamon and Péron, 1979; Y. Hamon, personal communication). Bacteriocin typing can be used for epidemiological purposes (Traub, 1980).

The antigenic structure of *S. marcescens* has been described. The present scheme consists of 28 somatic antigens (O1 to O28) and 25 flagellar antigens (H1 to H25) (Edwards and Ewing, 1972; Le Minor and Pigache, 1978; Traub and Fukushima, 1979a, b; Le Minor and Sauvageot-Pigache, 1981; Traub, 1991; Aucken et al., 1996). Subdivision of antigens O5 (into O5a, O5b, O5c), O10 (into O10a, O10b), and O16 (into O16a, O16b, O16c, O16d) has been proposed (Le Minor and Sauvageot-Pigache, 1981). Cross-reactions between factors O6 and O14 are very extensive and the distinction between these two factors does not seem worthwhile. Serovar O27 cross-reacts with the O4 serovar strain, and serovar O28 with the O5 serovar strain. The O-typing scheme was improved by separating capsular material from O-antigen (Gaston and Pitt, 1989a, b). H antigens are monophasic in *S. marcescens* (Aucken et al., 1996).

Four serovars (O1:H1, O2:H1, O3:H1, and O4:H1), all sharing a common H antigen, were described among *S. ficaria* strains (Grimont and Deval, 1982).

Resistance to cephalothin, colistin, and polymyxin (with respect to achievable serum levels of antibiotics) is very frequent in the genus and almost constant in *S. marcescens*. With the antibiotic disk method, a zone phenomenon develops around disks impregnated with colistin and polymyxin: the inhibition zone contains colonies close to the disk. However, this zone phenomenon is not restricted only to *Serratia*. Resistance to tetracycline and ampicillin is very frequent in *S. marcescens* and rare in other *Serratia* species. Plasmid-determined resistance to aminoglycoside antibiotics, carbenicillin, chloramphenicol, trimethoprim, sulfonamides, and mercury ions can be found in clinical strains of *S. marcescens*. "Third generation" cephalosporins are still active on *S. marcescens* and in a multicenter survey in the USA, fewer than 8% of *S. marcescens* isolates were resistant to piperacillin, 3–4% were resistant to ceftazidime, ceftriaxone, and/or cefotaxime, and 0.3% were resistant to imipenem (Jones, 1998). Resistance to cetyl trimethylammonium chloride (1.5 mg/ml) and thallus acetate (0.8 mg/ml) is very frequent (Grimont et al., 1977b). Of all the *Serratia* species, *S. marcescens* is the most resistant to antibiotics, antiseptics, and metal ions; *S. plymuthica* is the least resistant to these antimicrobials.

Healthy humans are not often infected by *Serratia*. *S. marcescens* is a prominent opportunistic pathogen for hospitalized human patients. At present, *S. marcescens* is the only known nosocomial species of *Serratia*. Clinically, *Serratia* infections do not differ from infections by other opportunistic pathogens (von Graevenitz, 1980). Other *Serratia* species can be involved in respiratory tract infection or colonization and septicemia, especially when these bacteria are accidentally injected into the body (e.g., contaminated perfusion or irrigation liquid) (Grimont and Grimont, 1978b).

S. marcescens and *S. liquefaciens* are known to infect and cause mortality in a variety of insects which can be serious pests of crops, ornamentals, and turf throughout the world (Klein and Kaya, 1995). Commercial utilization of *S. entomophila* against the grass grub *Costelytra zealandica* in New Zealand pastures has been achieved (Klein and Jackson, 1992). This bacterium turns the grubs a honey or amber color. Pathogenic strains of *S. entomophila* colonize the larva gut, adhere to the crop, and induce starvation, which causes depletion of the fat bodies. Pathogenicity is correlated with the production of lecithinase, proteinase, and chitinase (Kaska, 1976; Lysenko, 1976).

Mastitis in cows and other animal infections have been associated with *Serratia* species (Grimont and Grimont, 1978b). Pathogenicity in experimental animals is of the type expected of a Gram-negative bacterium. Experimental depression of phagocytic cell number or function in animals enhances susceptibility to *Serratia* infections (Simberkoff, 1980).

A typical hypersensitivity reaction is produced by inoculation of plants such as tobacco and king protea with *Serratia* (Lakso and Starr, 1970; Grimont et al. 1978b). *S. proteamaculans* was isolated from a leaf spot disease of *Protea cynaroïdes* (Paine and Stanfield, 1919) and *S. marcescens* (under the name *Erwinia amylovora* var. *alfalfae*) was isolated from a root disease of alfalfa (Shinde and Lukezic, 1974a).

Serratia species occur on plants, in the digestive tract of rodents (unpublished data), and in soil and water. *S. ficaria* is especially associated with the fig/fig-wasp ecosystem (Grimont et al., 1979b).

Enrichment and Isolation Procedures

Fecal samples (diluted with distilled water) or plant material washings are inoculated onto caprylate–thallus (CT) agar (Starr et al., 1976). After 2–5 d, the growth is removed by scraping and tested for deoxyribonuclease (DNase) activity. DNase-positive cultures are then purified by streaking on a nonselective medium (e.g., tryptic soy agar). Different colonial types are tested for DNase, and DNase-positive isolates are then thoroughly characterized and identified This procedure allows isolation of all *Serratia* species as defined in this chapter. *Providencia*, *Acinetobacter*, and fluorescent *Pseudomonas* strains can grow on CT agar when samples contain large numbers of these organisms. Other selective media based on DNase production and antibiotic resistance have been proposed (Cate, 1972; Berkowitz and Lee, 1973; Farmer et al., 1973). These antibiotic-containing media are efficient for the isolation of *S. marcescens* but may not be as reliable for more sensitive species (e.g., *S. plymuthica*).

Maintenance Procedures

For short-term preservation (several months), heavy suspensions of bacteria in sterile distilled water are made from bacterial growth scraped with a platinum loop from a nutrient agar slant. The suspensions are stored at room temperature. For longer preservation (several years), screw-capped tubes containing semi-

solid nutrient agar are stab-inoculated. After overnight growth at 30°C, the tubes are tightly closed and kept at room temperature in the dark. Maintenance failure may occur if the tube is not protected from desiccation by a rubber seal in the screw cap. Rubber corks dipped in melted paraffin wax may be preferred in place of screw caps.

Bacterial suspensions in brain–heart infusion supplemented with 50% glycerol and glass beads can be frozen at −80°C (cryoconservation). When needed, a glass bead can be taken without thawing the cryoconservation and transferred to a sterile broth for subculture. For long-term preservation (over 5 years), freeze-drying is preferred.

Procedures for Testing Special Characters

Carbon source utilization test This test is done by using Biotype-100 strips (bioMérieux, Craponne, France) that contains 99 pure carbon sources. Bottles of Biotype medium 1 are inoculated with a calibrated bacterial suspension (Grimont et al., 1996). The strips are incubated at 30°C for 4 d. Growth is scored visually after 2 and 4 days by comparison with the control cupule (without carbon source). The incubation day when growth is observed (1–4) is recorded for each cupule. Program Recognizer (Taxotron package, Institut Pasteur, Paris, France) can be used to enter the Biotype-100 data in an Apple Macintosh for automatic identification (Grimont et al., 1996).

Glucose oxidation test A 1-liter portion of glucose oxidation medium is composed of basal medium containing 8 g of nutrient broth (Difco Laboratories, Detroit, Mich.), 0.02 g of bromcresol purple, and 0.62 g of $MgSO_4 \cdot 7H_2O$ (2.5 mM). To 9.2 ml of autoclaved (121°C, 15 min) basal medium is added 0.4 ml of a filter-sterilized 1 M D-glucose solution (final concentration, 40 mM). This medium is supplemented with 0.4 ml of a fresh, sterile 25 mM iodoacetate solution (final concentration, 1 mM). The glucose oxidation medium is distributed (0.5–ml portions) into glass tubes (11 by 75 mm), which are plugged with sterile cotton wool. Bacteria grown overnight at 20 or 30°C on tryptocasein soy agar (Biorad, Marnes-la Coquette, France) supplemented with 0.2% (w/v) D-glucose are collected with a platinum loop, suspended in a sterile 2.5 mM $MgSO_4$ solution and adjusted to an absorbance at 600 nm of about 4. Glucose oxidation medium is then inoculated with 50 µl of bacterial suspension and vigorously shaken at 270 strokes per minute overnight at 20 or 30°C. The test is positive when a yellow color develops (acid production). In a negative test, the medium remains purple. When negative, the glucose oxidation test is repeated in the presence of 10 µM pyrroloquinoline quinone (PQQ). The control strains used are the type strains of *S. marcescens* (positive without requirement for PQQ), *S. liquefaciens* (positive only when PQQ is supplied), and *Hafnia alvei* (negative) (Bouvet et al., 1989).

Gluconate- and 2-ketogluconate dehydrogenase tests The gluconate dehydrogenase test is done as follows (Bouvet et al., 1989). Bacteria are grown overnight at 20°C on tryptocasein soy agar supplemented with 0.2% D-gluconate, then collected with a platinum loop and suspended in sterile distilled water to an absorbance (at 600 nm) of about 4. The reaction medium contains 0.2 M acetate buffer (pH 5), 1% (w/v) Triton X-100, 2.5 mM $MgSO_4$, 75 mM gluconate and (added immediately before use) 1 mM iodoacetate. A control medium contains the same ingredients except gluconate. The reaction medium and the control medium are dispensed (100-µl portions) into 96-well microtiter plates (Dynatech AG, Denkendorf, FRG). Bacterial suspensions (10 µl) are added to the reaction and control media and the microtiter plates are incubated at 20°C for 20 min. Then, 10-µl portions of a 0.1 M potassium ferricyanide solution (kept in the dark at room temperature for no longer than 1 week) are added to the wells and the plates are gently shaken and incubated at 20°C for 40 min. Then 50-µl portions of a reagent ($Fe_2(SO_4)_3$, 0.6 g; SDS, 0.36 g; 85% phosphoric acid, 11.4 ml; distilled water to 100 ml) are added to the wells. The plates are examined for the development of a green to blue color (due to Prussian blue) within 15 min at room temperature. The color in the uninoculated control medium remains yellow. The suggested control strains used are *Escherichia coli* K12 (negative) and the type strain of *Serratia marcescens* (positive).

The 2-ketogluconate dehydrogenase test is the same as above, except that the control and reaction media are adjusted to pH 4.0 and 2-ketogluconate is used in place of gluconate in the reaction medium. Suggested control strains are *Escherichia coli* K12 (negative) and the type strain of *Serratia marcescens* (positive at 20°C, not at 30°C) (Bouvet et al., 1989).

Glycerol dehydrogenase test (Bouvet et al., 1995a) For the detection of glycerol dehydrogenase, bacteria are grown overnight at 30°C on tryptocasein soy agar plates (TCS, BioRad, Marnes-la-Coquette, France) supplemented with 1% glycerol or 70 mM hydroxyacetone. Bacterial growth is collected, suspended in reaction buffer [0.1 M K_2CO_3 and 30 mM $(NH_4)_2SO_4$, adjusted to pH 9.0] to an absorbance of 0.6, and bacterial suspensions are dispensed into 96-well microtiter plates. Then, 30-µl aliquots of a reagent (NAD^+, 210 mg; glycerol, 600 ml; nitro-blue tetrazolium, 42 mg; phenazine methosulfate, 2 mg; distilled water to 10 ml) are added to the wells and incubated in the dark with shaking. The plate is examined for a purple color developed within 15 to 30 min (presence of a glycerol dehydrogenase). The color in the uninoculated control medium remains yellow. Suggested control strains are the type strain of *Serratia liquefaciens* (glycerol dehydrogenase induced by glycerol, not by hydroxyacetone) and the type strain of *Enterobacter asburiae* (dehydrogenase induced by hydroxyacetone, not by glycerol) (Bouvet et al., 1995a).

Voges–Proskauer test (Richard's modification) Clark and Lubs medium (BBL) is dispensed in large 22 × 215 mm tubes (0.5 ml per tube) and inoculated with 0.05 ml of a heavy bacterial suspension in distilled water. After incubation at 30°C for 18 h, 0.5 ml of α-naphthol solution (6% w/v alcoholic solution) and 0.5 ml of 4 M NaOH are added. The tubes are shaken, heated a few seconds in a Bunsen flame, and examined for a red color (Richard, 1972).

Tetrathionate reduction The medium of Le Minor et al. (1970a) contains: peptone (Difco), 10.0 g, NaCl, 5.0 g; $K_2S_4O_6$, 5.0 g; bromothymol blue (0.2% aqueous solution), 25 ml; and distilled water to 1 liter. Adjust the pH to 7.4, sterilize by filtration, and dispense into 12 × 120 mm tubes (4 ml per tube). The size of the tubes (for a rather limited aeration) is critical. Inoculated tubes are incubated at 30°C for 24 h and examined for a yellow color (tetrathionate reduction).

β-Xylosidase Paper disks (0.5 cm) are loaded with 0.1 ml of a 2% (w/v) aqueous solution of *p*-nitrophenyl-β-D-xylopyranoside and kept dry in a tightly-capped flask at 4°C. The test is performed exactly like the β-galactosidase test, but with *p*-nitrophenyl-β-D-xylopyranoside disks in place of ONPG disks (Brisou et al., 1972).

H-Immobilization test The motility of each isolate to be typed must be enhanced by passage through a 0.3% semisolid agar U-tube.

The following autoclaved semisolid medium is dispensed in 2.0-ml volumes into small (92 × 13 mm) screw-capped tubes: tryptic peptone, 20.0 g; D-mannitol, 2.0 g; KNO_3, 1.5 g; phenol red solution (1%), 4 ml; agar, 4.5 g. distilled water, 1000 ml; pH 7.4. The tubes of semisolid medium are melted (boiling water bath), cooled to 50°C in a water bath, supplemented with 0.05 ml of each serum dilution under sterile conditions, and allowed to gel.

Tubes with serum dilutions (and control tubes without serum) are stab-inoculated with a highly motile culture. After overnight incubation, tubes are examined for immobilization. This H-immobilization test is very specific and much easier to perform than the classical H-agglutination (Le Minor and Pigache, 1977).

Differentiation of the genus *Serratia* from other genera

Table BXII.γ.265 provides the primary characteristics that can be used to differentiate the genus *Serratia* from biochemically similar taxa.

Taxonomic Comments

A number of changes have been made since the eighth edition of the *Manual of Determinative Bacteriology*, in which it was indicated that the genus *Serratia* was composed of only one species, *S. marcescens* (the type species). Objective approaches such as numerical taxonomy and DNA relatedness applied to strains recovered from diverse habitats delineated an increasing number of species in the genus. Seven species were mentioned in the first edition of the *Bergey's Manual of Systematic Bacteriology* (Grimont and Grimont, 1984) and 10 species were mentioned in the second edition of *The Prokaryotes* (Grimont and Grimont, 1995). Ten species are currently known to belong in the genus *Serratia*.

Transfer of *Enterobacter liquefaciens* to the genus *Serratia* was first proposed by Barbe (1969) and supported by studies on bacteriocin cross-reactions between *S. marcescens* and *E. liquefaciens* (Hamon et al., 1970). Valid publication of the new combination *S. liquefaciens* followed a numerical taxonomy study (Bascomb et al., 1971).

A phenon named "biovar 2" (Bascomb et al., 1971) and "phenon B" (Grimont and Dulong de Rosnay, 1972) was thought identical to *"Bacterium rubidaeum"* Stapp 1940 and named *S. rubidaea* (Ewing et al., 1973). The same phenon was also identified as *S. marinorubra* Zobell and Upham 1944 (Grimont et al., 1977b). *S. rubidaea* and *S. marinorubra* were based on different type strains (ATCC 27593 and ATCC 27614, respectively). The *Approved Lists of Bacterial Names*, however, gives both names (*S. rubidaea* and *S. marinorubra*) with the same type strain (viz. ATCC 27614, the type strain of *S. rubidaea*). Hence, both names, which were subjective synonyms, are now objective synonyms and redundant. To avoid further confusion, the name *S. rubidaea* (Stapp) Ewing (1986a) should now be used exclusively to designate the same (*S. rubidaea–S. marinorubra*) taxon.

The ancient species *S. plymuthica* (Lehmann and Neumann 1896) Breed, Murray, and Hitchens 1948 was shown to be a valid species by numerical taxonomy (Grimont et al., 1977b) and by DNA–DNA hybridization (Grimont et al., 1978a).

Three species, *S. odorifera* (Grimont et al., 1978a), *S. ficaria* (Grimont et al., 1979b), and *S. entomophila* (Grimont et al., 1988), were defined by DNA relatedness, carbon source utilization tests, and by standard biochemical tests. DNA relatedness studies have shown that *S. marcescens*, *S. plymuthica*, *S. rubidaea*, *S. odorifera*, and *S. ficaria* are homogeneous and discrete genomospecies (Steigerwalt et al., 1976; Grimont et al., 1978a, 1979b, 1988).

S. liquefaciens sensu lato was shown to be heterogeneous (Steigerwalt et al., 1976) and later found to be composed of several genomospecies. One biovar (Clc) of *S. liquefaciens* was identified as *Erwinia proteamaculans* (Paine and Stanfield 1919) Dye 1966a and renamed *S. proteamaculans* (Grimont et al., 1978b). When DNA binding ratios were examined without studies on the thermal stability of hybridized molecules, *S. proteamaculans* was thought to be a subjective synonym of *S. liquefaciens* (Grimont et al., 1978b). Reexamination of DNA relatedness (including thermal stability studies) in *S. liquefaciens sensu lato* disclosed at least

[e]Determined in Biotype-100 (B) or minimal agar (M).

three genomospecies: *S. liquefaciens sensu stricto*, *S. proteamaculans* (Grimont et al., 1982b), and a third group containing strain ATCC 14460 and named *S. grimesii* (Grimont et al., 1982a, b).

A group of strains called "*Citrobacter* lysine+" or "*Citrobacter*-like" was found to be significantly related to the genus *Serratia* in DNA–DNA hybridization studies (Crosa et al., 1974). This genomospecies has been named *Serratia fonticola* Gavini et al. 1979; however, a difficulty is that *S. fonticola* does not have the key characteristics of the genus *Serratia*. Furthermore, *Serratia* phages that are active on strains of any *Serratia* species (as defined herein) have been found to be inactive on all *S. fonticola* strains tested (unpublished data). Bacteriocins from *Serratia* are also inactive on *S. fonticola* (Hamon, personal communication). However, the 16S rRNA gene sequence of *S. fonticola* branches within the psychrotolerant *Serratia* cluster (*S. liquefaciens*, *S. proteamaculans*, *S. grimesii*, and *S. plymuthica*) and this justifies the inclusion of *S. fonticola* in the genus *Serratia* (Dauga et al., 1990).

Differentiation of the species of the genus *Serratia*

The differential characteristics of the species of *Serratia* are indicated in Table BXII.γ.266. Other characteristics of the species are listed in Table BXII.γ.267.

List of species of the genus Serratia

1. **Serratia marcescens** Bizio 1823, 288[AL]
mar.ces′ cens. M.L. v. *marcesco* to fade; L. part. adj. *marcescens* fading away.

The cell morphology and colonial morphology are as given for the genus. Prodigiosin or pyrimine can be produced.

Physiological and nutritional characteristics are presented in Tables BXII.γ.266 and BXII.γ.267.

A biotyping system based on pigment production, tetrathionate reduction and utilization of *meso*-erythritol, trigonelline, quinate, benzoate, 3-hydroxybenzoate, 4-hydroxybenzoate, and DL-carnitine as sole carbon sources, has been described (Grimont and Grimont, 1978a). DL-carnitine is not in Biotype-100 strips and can be replaced by D-malate and *meso*-tartrate. Groups of biovars (called biogroups) (Table BXII.γ.268) correspond to definite, nonoverlapping sets of serovars (Table BXII.γ.269) (Grimont et al., 1979a).

Nonpigmented biogroups A3 and A4 are ubiquitous. Nonpigmented biogroups A5/8 and TCT are almost confined to hospitalized patients. Pigmented biogroups Al and A2/6 are found in the natural environment and occasionally in human patients.

The mol% G + C of the DNA is: 57.5–60 (T_m, Bd).

Type strain: ATCC 13880, CIP 103235, DSM 30121, DSM 47, JCM 1239, NCDC 813-60, NCIB 9155, NCTC 10211.

GenBank accession number (16S rRNA): AJ233431, M59160.

2. **Serratia entomophila** Grimont, Jackson, Ageron and Noonan 1988, 5[VP]
en.to.mo′phi.la. Gr. n. *entomon* insect; Gr. v. *phylein* love; L. fem. adj. *entomophila* insect loving.

The cell morphology and colonial morphology are as given for the genus. Prodigiosin is not produced.

Physiological and nutritional characteristics are presented in Tables BXII.γ.266 and BXII.γ.267.

Two biotypes can be delineated (Table BXII.γ.270).

Isolated from larvae of *Costelytra zealandica* (grass grub) with amber disease, and from the environment. No strain has been identified as being involved in a human, animal (other than insect), or plant disease.

The mol% G + C of the DNA is: 58 (T_m).

Type strain: A1, ATCC 43705, CIP 102919, DSM 12358.

GenBank accession number (16S rRNA): AJ233427.

3. **Serratia ficaria** Grimont, Grimont and Starr 1981d, 216[VP] (Effective publication: Grimont, Grimont and Starr 1979b, 282.)
fi.ca′ri.a. M.L. fem. adj. *ficaria* of figs.

The cell morphology and colonial morphology are as given for the genus. Prodigiosin is not produced. Cultures give off a musty, potato-like odor.

Physiological and nutritional characteristics are presented in Tables BXII.γ.266 and BXII.γ.267.

Associated with the fig/fig-wasp biological cycle. Occasionally found on plants other than fig trees.

The mol% G + C of the DNA is: 59.6 (T_m).

Type strain: ATCC 33105, CIP 79-23, DSM 4569, ICPB 4050, JCM 1241.

GenBank accession number (16S rRNA): AJ233428, AB004745.

4. **Serratia fonticola** Gavini, Ferragut, Izard, Trinel, Leclerc, Lefebvre and Mossel 1979, 98[AL]
fon.ti′co.la. M.L. n. *fons, fontis* spring, fountain; L. suff. *-cola* dweller; M.L. n. *fonticola* spring-dweller.

The cell morphology and colonial morphology are as given for the genus. Prodigiosin is not produced.

Does not share the key characteristics of the genus *Serratia*.

Physiological and nutritional characteristics are presented in Tables BXII.γ.266 and BXII.γ.267.

Occurs in freshwater.

The mol% G + C of the DNA is: 48.8–52.5 (T_m).

Type strain: ATCC 29844, CIP 78.64, CCUG 37824, DSM 4576, JCM 1242, LMG 7882.

GenBank accession number (16S rRNA): AJ233429.

[a]Data from Grimont and Grimont (1995) and Gavini et al. (1979). For symbols see standard definitions.

5. **Serratia grimesii** Grimont, Grimont and Irino 1983b, 438[VP] (Effective publication: Grimont, Grimont and Irino 1982a, 73.)
gri.me′ sii. M.L. gen. masculine form of Grimes.

S. grimesii has been isolated from the natural environment and from human clinical specimens.

Physiological and nutritional characteristics are presented in Tables BXII.γ.266 and BXII.γ.267.

Biogroup ADC might represent a subspecies of *S. grimesii.*

The mol% G + C of the DNA is: not determined.

Type strain: ATCC 14460, CIP 103361, DSM 30063, IFO 13537, JCM 5910.

GenBank accession number (16S rRNA): AJ233430.

6. **Serratia liquefaciens** (Grimes and Hennerty 1931) Bascomb, Lapage, Willcox and Curtis 1971, 293[AL] (*"Aerobacter liquefaciens"* Grimes and Hennerty 1931, 93.)
li.que.fa′ ciens. M.L. part. adj. *liquefaciens* dissolving.

The cell morphology and colonial morphology are as given for the genus. Prodigiosin is not produced.

Physiological and nutritional characteristics are presented in Tables BXII.γ.266 and BXII.γ.267.

S. liquefaciens sensu lato was composed of several biovars and some of these were found to constitute genomospecies which were subsequently given species status: biovar C1ab (including the type strain of *S. liquefaciens*) corresponded to *S. liquefaciens sensu stricto*; biovars C1c (including the type strain of *S. proteamaculans*), EB, RB, and RQ corresponded to *S. proteamaculans*; and biovars C1d and ADC corresponded to *S. grimesii* (Table BXII.γ.271) (Grimont et al., 1977b, 1982a, b).

S. liquefaciens is the most prevalent *Serratia* species in the natural environment (plants, digestive tract of rodents). Occasionally encountered as an opportunistic pathogen.

The mol% G + C of the DNA is: 53–54 (T_m, Bd).

Type strain: ATCC 27592, CIP 103238, DSM 4487, JCM 1245, LMG 7884, NCTC 12962.

GenBank accession number (16S rRNA): AJ306725, AB004752.

It should be mentioned that the strain formerly considered to be the type strain of *"Aerobacter liquefaciens"* or *"Aerobacter lipolyticus"* by Grimes (1961) was ATCC 14460 (now the type strain of *S. grimesii*). Since this strain was considered atypical compared to other strains labeled as *S. liquefaciens*, another strain (ATCC 27592) was given as type strain of *S. liquefaciens* in the Approved Lists.

7. **Serratia odorifera** Grimont, Grimont, Richard, Davis, Steigerwalt and Brenner 1978a, 461[AL]
o.do.ri.fe′ra. M.L. fem. adj. *odorifera* bringing odors, fragrant.

The cell morphology and colonial morphology are as given for the genus. Prodigiosin is not produced. Cultures give off a musty, potato-like odor.

Physiological and nutritional characteristics are presented in Tables BXII.γ.266 and BXII.γ.267. Two biovars can be recognized (Table BXII.γ.272).

The capsular antigen reacts with *Klebsiella* antisera K4 or K68.

Rare opportunistic pathogen. Occasionally isolated from plants or food.

The mol% G + C of the DNA is: 54.6 (T_m).

Characteristics	1b	2
Growth on:[b]		
D-Arabitol	+	−
L-Arabitol	−	+
D-Malate	−	d
D-Sorbitol	−	d
Quinate	+	d
D-Xylose	−	+

[a]For symbols see standard definitions.

[b]The type strain corresponds to biotype 1.

Type strain: ATCC 33077, CIP 79-1, DSM 4582, ICPB 3995, NCTC 11214.

GenBank accession number (16S rRNA): AJ233432.

8. **Serratia plymuthica** (Lehmann and Neumann 1896) Breed, Murray and Hitchens 1948, 481[AL] (*Bacterium plymuthicum* (sic) Lehmann and Neumann 1896, 264.)
ply.mu'thi.ca. M.L. adj. *plymuthica* pertaining to Plymouth, UK.

The cell morphology and colonial morphology are as given for the genus. Prodigiosin is produced by most strains.

Physiological and nutritional characteristics are presented in Tables BXII.γ.266 and BXII.γ.267.

Most *S. plymuthica* strains studied were isolated from freshwater. Very rarely found in human sputum. No human infection reported.

The mol% G + C of the DNA is: 53.5–56.5 (T_m).

Type strain: ATCC 183, CIP 103239, DSM 4540, JCM 1244.

GenBank accession number (16S rRNA): AJ233433.

S. plymuthica is cited on the Approved Lists of Bacterial Names (Skerman et al., 1980) as *Serratia plymuthica* (Dyar 1895) Bergey, Harrison, Breed, Hammer and Huntoon 1923, 88. This is incorrect, for reasons discussed by Grimont et al. (1977b).

9. **Serratia proteamaculans** (Paine and Stansfield 1919) Grimont, Grimont and Starr 1978b, 503[AL] (*Pseudomonas proteamaculans* Paine and Stansfield 1919, 38.)
pro.te.a.ma.cu'lans. M.L. n. *Protea* a plant generic name; L. v. *maculo* to spot; M.L. part. adj. *proteamaculans* spotting *Protea.*

S. proteamaculans and *S. liquefaciens* were thought to be synonymous based on DNA relatedness (Grimont et al., 1978b). However, subsequent observation of significant thermal instability of reassociated DNA fragments supported the separation of both species (Grimont et al., 1982b).

The cell morphology and colonial morphology are as given for the genus. Prodigiosin is not produced.

Physiological and nutritional characteristics are presented in Tables BXII.γ.266 and BXII.γ.267.

S. proteamaculans is found in the natural environment (plants, wild rodents, insects, and water) but exceptionally from human clinical specimens).

The mol% G + C of the DNA is: not determined.

Type strain: ATCC 19323, CIP 103236, DSM 4543, NCPPB 245.

According to J-P. Euzeby (http://www.bacterio.cict.fr/corrections2.html), the spelling should have been *proteimaculans.* However, since the name appeared in the Approved Lists, no correction is allowed.

a. **Serratia proteamaculans** *subsp.* **proteamaculans** (Paine and Stansfield 1919) Grimont, Grimont and Starr 1978b, 503[AL] (*Pseudomonas proteamaculans* Paine and Stansfield 1919, 38.)

The subspecies includes biovars C1c, EB, and RB. The type strain belongs to biotype C1c. Differential characteristics are given in Table BXII.γ.271.

The mol% G + C of the DNA is: not determined.

Type strain: ATCC 19323, CIP 103236, DSM 4543, NCPPB 245

GenBank accession number (16S rRNA): AJ233434.

b. **Serratia proteamaculans** *subsp.* **quinovora** Grimont, Grimont and Irino 1983b, 438[VP] (Effective publication: Grimont, Grimont and Irino 1982a, 71.)
qui.no'vo.ra. M.L. *quinate,* from Spanish *quina* quinine; and L. v. *voro* to devour; M.L. fem. adj. *quinovora* quinate devouring.

This subspecies corresponds to biotype RQ. Quinate utilization was observed for all strains of this subspecies in a minimal agar when an unwashed inoculum was used. In Biotype-100 strips, no growth is observed on quinate when Biotype Medium 1 is used, some strains grow from quinate when Biotype Medium 2 (containing more growth factors) is used.

The mol% G + C of the DNA is: not determined.

Type strain: ATCC 33765, CIP 81-95, DSM 4597.

GenBank accession number (16S rRNA): AJ233435.

10. **Serratia rubidaea** (Stapp 1940) Ewing, Davis, Fife and Lessel 1973, 224[AL] (*"Bacterium rubidaeum"* Stapp 1940, 259; *Serratia marinorubra* Zobell and Upham 1944, 255.)
ru.bi'dae.a. L. *Rubus idaeus* raspberry, contracted and made to agree in gender with *Serratia.*

The cell morphology and colonial morphology are as given for the genus. Prodigiosin is produced by most strains.

Physiological and nutritional characteristics are presented in Tables BXII.γ.266 and BXII.γ.267.

Three biotypes (B1, B2, B3) correspond to subspecies "*S. rubidaea* subsp. *burdigalensis*", "*S. rubidaea* subsp. *rubidaea*", and "*S. rubidaea* subsp. *colindalensis*" (Grimont et al., manuscript in preparation) (Table BXII.γ.273).

S. rubidaea strains are rarely isolated, either in the natural environment or in human patients. May be found in ripe coconuts (Grimont et al., 1981c).

The mol% G + C of the DNA is: 53.5–58.5 (T_m).

Type strain: Ewing 2199-72, ATCC 27593, CIP 103234, DSM 4480, JCM 1240.

GenBank accession number (16S rRNA): AB004751, AJ233436.

TABLE BXII.γ.271. Identification of species in the *Serratia liquefaciens* complex[a]

[b]The biotypes were shown to correspond to subspecies designated as "*S. rubidaea* subsp. *burdigalensis*" (B1), "*S. rubidaea* subsp. *rubidaea*" (B2), and "*S. rubidaea* subsp. *colindalensis*" (B3).

Genus XXXV. **Shigella** *Castellani and Chalmers 1919, 936*[AL]

NANCY A. STROCKBINE AND ANTHONY T. MAURELLI

Shi.gel' la. M.L. dim. *-ella* ending; M.L. fem. n. *Shigella* named after K. Shiga, the Japanese bacteriologist who first discovered the dysentery bacillus.

Straight rods, 1–3 × 0.7–1.0 μm, that conform to the general definition of the family *Enterobacteriaceae* and contain the enterobacterial common antigen. Gram negative. Nonmotile. Nonpigmented. Facultatively anaerobic, having both a respiratory and a fermentative type of metabolism. Catalase positive (with exceptions in *Shigella dysenteriae*). Oxidase negative. Chemoorganotrophic. **Ferment sugars without gas production** (a few exceptions produce gas). **Salicin, adonitol, and *myo*-inositol are not fermented**. Strains of *Shigella sonnei* ferment lactose and sucrose upon extended incubation; however, other species do not utilize these substances in conventional medium. **Do not utilize citrate, malonate, or sodium acetate** (with exceptions in *Shigella flexneri* for sodium acetate) as a sole carbon source. **Do not grow in KCN or produce H_2S. Do not decarboxylate lysine**. Reduce nitrates to nitrites. Intestinal pathogens of humans and other primates, causing bacillary dysentery. Based on 16S rDNA sequencing, shigellae belong in the *Gammaproteobacteria*.

The mol% G + C of the DNA is: 49–53 (Laskin and Lechevalier, 1981).

Type species: **Shigella dysenteriae** (Shiga 1898) Castellani and Chalmers 1919, 935, Epit. Spec. Cons. Opinion 11 of the Jud. Comm. 1954a, 149 (*Bacillus dysenteriae* Shiga 1898, 817.)

Further descriptive information

Phylogenetic and systematic treatment Scientific evidence accumulated to date strongly supports the view that *Shigella* species are biotypes/pathotypes or clones of *Escherichia coli*. As early as 1957, Luria and Burrous (1957) showed that *E. coli* and the majority of *Shigella* species are in the same fertility system and suggested that genetic recombination between these organisms could play a role in the evolution of some *Shigella* serotypes and, more generally, in the evolution of natural populations of these bacteria. In the early 1970s, Brenner et al. (1972a, 1973a) published findings from DNA–DNA reassociation studies that provided the first direct insights into the evolutionary relationships between shigellae and *E. coli*. These authors found that, with the exception of *S. boydii* 13 (see discussion under Taxonomic comments), *Shigella* species were as related to *E. coli* (>75% nucleotide similarity) as they were to each other.

Given the variability that occurs within the defined *E. coli* species, the question then is whether the four species of *Shigella* represent the evolution of new species from a common ancestor or whether these organisms are clones of *E. coli*. Findings from multilocus enzyme electrophoresis (MLEE) analyses strongly support the conclusion that shigellae are more appropriately regarded as pathotypes or clones of *E. coli*. Principal component analysis of 302 electrophoretic types (ETs) from more than 1600 human and animal isolates of *E. coli* and 123 strains of the four species of *Shigella* showed that the *Shigella* strains clustered within two of the three overlapping groups of *E. coli* strains detected, rather than forming a group apart from those comprised by *E. coli*, as would be expected of a distinct genus (Ochman et al., 1983). Furthermore, with the exception of *S. boydii* 13, strains representing all four species of *Shigella* did not cluster in groups corresponding to each species. A dendrogram of the 23 ETs from *Shigella* constructed by average linkage clustering revealed two major clusters each containing strains of three or more species; one group consisted of ETs representing *S. flexneri*, *S. dysenteriae*, and *S. boydii* strains and the other consisted of ETs representing strains from all four species, with *S. sonnei* being most distantly related (Ochman et al., 1983).

MLEE findings from the study by Pupo et al. (1997) also showed that strains from the four species of *Shigella* clustered in two separate groups, with one group containing strains from the majority of *Shigella* species and the other group containing only *S. flexneri* strains. With the exception of one *S. flexneri* serotype, the *Shigella* species appeared as clones within the *E. coli* species. Nucleotide sequence analysis of the housekeeping gene maltose dehydrogenase (*mdh*) (Pupo et al., 1997) and analysis of restriction fragment length polymorphisms of rDNA (ribotyping) (Rolland et al., 1998) also yielded largely similar clustering of shigellae, but showed somewhat different distributions of the *Shigella* spp. among the *E. coli* phylogenetic groups.

A careful analysis of 16S ribosomal DNA sequences by Cilia et al. (1996) also placed shigellae and *E. coli* in the same phylogenetic group, supporting the concept that *Shigella* species and *E. coli* are five nomenspecies that represent a single genomospecies. In fact, the variation of the 16S ribosomal RNA genes in the seven *rrn* operons of a single strain of *E. coli* shared a clade with *S. dysenteriae*, *S. flexneri*, and *S. sonnei* sequences. There were informative base alleles that were shared by both *E. coli* and *Shigella* species.

Recent findings reported by Pupo et al. (2000) from the examination of nucleotide sequence similarity at eight housekeeping genes in four regions around the chromosome of *Shigella* and selected nonpathogenic *E. coli* strains (ECOR set) revealed three clusters of closely related strains, each including exclusively *Shigella* strains but from more than one species. *S. sonnei* and three *S. dysenteriae* strains from *S. dysenteriae* serotypes 1, 8, and 10 fell outside the three main clusters but were well within the population structure of *E. coli*. The presence of these seven different groups (clusters 1–3, *S. sonnei*, *S. dysenteriae* serotypes 1, 8, and 10) within *E. coli* suggests that the *Shigella* phenotype has arisen as many as seven times from ancestors that were *E. coli*. Pupo et al. (2000) propose that the many independent origins of the *Shigella* phenotype are an example of convergent evolution. Phenotypes that may have arisen by convergent evolution include the loss of catabolic pathways involving lactose fermentation, mucate utilization, lysine decarboxylation, the loss of motility, and the acquisition of the invasion plasmid (Pupo et al., 2000).

It has been suggested that *E. coli* arose from a common ancestor with *Salmonella* and diverged largely as the result of the acquisition of multiple genomic fragments (Lawrence and Ochman, 1998). It appears that *Shigella* differs from *E. coli* largely by the loss of genomic fragments. Maurelli et al. (1998) showed that shigellae lack a large fragment of the genome relative to *E. coli* K-12. It is interesting to note that the missing fragment included the *cadA* gene discussed in more detail below. The same pattern has been noted with another genomic fragment that derives from a cryptic prophage in *E. coli* K-12 and includes the *ompT* gene (Nakata et al., 1993). This gene encodes a surface protease that when introduced into *Shigella* inhibited the ability of the organism to spread among host cells. Another fascinating deletion occurs in *S. sonnei*. A large portion of the O-antigen gene cluster has been excised, leaving remnants of genes normally found at the ends of the cluster fused together (Lai et al., 1998). The clone carries a plasmid that has O-antigen genes that apparently arose in *Plesiomonas shigelloides* (Houng and Venkatesan, 1998; Chida et al., 2000). It has been postulated that the acquisition of the new O-antigen was a prerequisite for *S. sonnei* emerging in its modern niche and that this might have occurred about 10,000 years ago (Lai et al., 1998).

In contrast to the concept of species being defined as a group having a monophyletic origin, a species may be defined as a group of organisms sharing genetic drift (Hey, unpublished studies). By this latter definition, *Shigella* species might be classified independently of *E. coli*. Factors that affect the sharing of genetic drift among bacteria are natural selection and recombinant exchange of DNA. Shigellae are considered to be host-adapted to primates and thus have a narrower niche than *E. coli*. It is difficult to conclusively define species of bacteria based on recombination-exchange partners. Islands of DNA that clearly came from other species can frequently be found in bacterial genomes. However, it does appear that the frequency of recombination is proportional to the closeness of the species. Matsutani and Ohtsubo (1993) surveyed the distribution of five insertion elements (IS1, IS600, IS629, IS630, and IS640) originally found in *S. sonnei*. In general, the elements were found in high copy numbers in *S. sonnei*, *S. dysenteriae*, *S. flexneri*, and *S. boydii* (often more than 20 copies per genome), in moderate numbers in *E. coli*, and occa-

sionally, albeit rarely, in other *Enterobacteriaceae*. Thus, it may be that *Shigella* species are in the process of drifting apart from *E. coli*. The alternative hypothesis is that the insertion elements are more readily duplicated within clones that they exist in rather than across clones. However, the conclusion is the same since it would mean that the elements are more ancient in shigellae and this is an example of genetic drift that is not shared with *E. coli*.

If history were to be rewritten with the privilege of having our current understanding of the pathogenesis and diversity extent within *E. coli*, a very different nomenclature for *Shigella* would undoubtedly be adopted. Although phylogenetically it would be better to treat shigellae as pathotypes of *E. coli*, the members of the genus *Shigella* continue to be divided for historical and medical purposes into four species or subgroups: *S. dysenteriae* (subgroup A), *S. flexneri* (subgroup B), *S. boydii* (subgroup C), and *S. sonnei* (subgroup D). The useful information communicated about the disease caused by these organisms (shigellosis) through the genus epithet *Shigella* has preserved and will likely continue to preserve the current nomenclature until such time when there is a greater need to communicate the natural relationships that exist between these strains.

Biochemical characteristics of the genus are listed in Table BXII.γ.274. The biochemical reactions that are useful for differentiating the four species of *Shigella* are listed in Table BXII.γ.275. The ability to ferment D-mannitol is a particularly important differential biochemical trait for classifying the shigellae. Although exceptional strains occur, members of subgroup A are unable to ferment D-mannitol, while members of the other subgroups (B, C, and D) are able to ferment this sugar. Members of the genus *Shigella* have distinctive antigenic structures by which they are divided into a variety of serotypes and subserotypes. It is the combination of biochemical traits, particularly the D-mannitol phenotype, and antigenic properties that have guided the classification of members of this genus. The current schema for classifying *Shigella*, which recognizes 49 serotypes and subserotypes, is shown in Table BXII.γ.276.

Cell morphology Shigellae are nonmotile, Gram-negative rods with rounded ends. They are typically 1–3 μm in length and 0.7–1 μm in diameter. Fig. BXII.γ.209 shows negatively stained preparations of *S. dysenteriae* 1 and *S. flexneri* 2a. The bacterial cells in this figure are nonflagellated, which is typical of the members belonging to this genus. Under certain culture conditions, however, some cells in a culture have been observed to express flagella. See the section below on fine structure for a discussion of exceptions to the presence of flagella.

Cell wall composition The cell walls of shigellae resemble those of other Gram-negative bacteria in structure, composition, and endotoxic activity. When serologically characterizing living (unheated) isolates that are biochemically consistent with *Shigella*, it is important to be aware that living bacterial cells of certain strains of *Shigella* can produce a substance that will block their agglutination with O antisera. The masking effects of this substance, originally referred to as a K antigen of the B variety or B antigen, can be inactivated by heat. Treatment of nonagglutinable cultures at 100°C for 1 h restores their ability to be agglutinated by O antisera. Blocking substances also occur in certain *E. coli* strains and were shown by Ørskov et al. (1977) to be chemically and antigenically indistinguishable from the O antigens present in the cell-wall lipopolysaccharides of these bacteria. Blocking substances (B antigens) are no longer recognized as distinct antigens; however, their presence in unheated cells remains important from a practical standpoint.

[a]For symbols see standard definitions. Adapted from findings reported by Ewing (1971) based on the examination of 5166 cultures representative of all four species. Unless specified otherwise, results are for 48 h incubation at 36° ± 1°C.

[b]Some strains of some serotypes of *S. dysenteriae*, *S. flexneri*, and *S. boydii* produce indole while strains of other serotypes are always negative. *S. sonnei* is always negative.

[c]Strains of *S. boydii* 13 and *S. sonnei* are positive.

[d]Some biotypes of *S. flexneri* 6 are positive; positive strains of *S. boydii* 13 and 14 have been described.

[e]Strains of *S. sonnei* are usually positive after several days of incubation; positive strains of *S. flexneri* 2a, *S. boydii* 9, and *S. boydii* 15 have been described. Some strains of *S. dysenteriae* 1 ferment lactose slowly; however, all are positive for β-galactosidase.

[f]Strains of *S. dysenteriae* are negative; negative biotypes of *S. flexneri* 4a (*"S. rabaulensis"*, *"S. rio"*) and *S. flexneri* 6 (Newcastle biotype) occur; negative biotypes of *S. sonnei* occur rarely.

[g]Strains of *S. sonnei* are usually positive after several days of incubation.

[h]ONPG, *o*-nitrophenyl-β-D-galactopyranoside.

[i]Strains of *S. dysenteriae* 1 and *S. sonnei* are positive; some positive strains of *S. flexneri* 2a and *S. boydii* 9 have been described.

Fine structure

Flagella By standard methods (radial spread from the site of inoculation in medium containing 0.3–0.4% agar), shigellae are nonmotile. Over the past decade, various investigators have shown that *Shigella* strains have the genes involved in producing flagella and, under certain conditions, can express these genes.

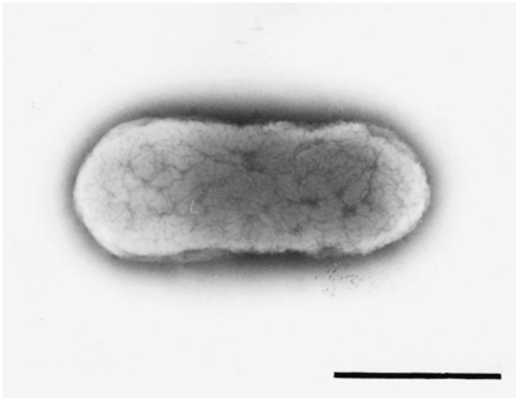
Direct evidence for the existence of flagellum-related sequences in *Shigella* was reported by Tominaga et al. (1994), who identified and characterized cryptic genes for flagellin (*fliC*) in *S. flexneri* and *S. sonnei*. The cloned *fliC* gene from *S. flexneri* produced normal-type flagella when introduced into a strain of *E. coli* deleted for *fliC*, while the cloned *fliC* gene from *S. sonnei* produced curly-type flagella in this host strain. Findings from comparisons of nucleotide sequences of the *fliC* genes from *S. flexneri* and *S. sonnei* with those from *E. coli* and *Salmonella* serotype Typhimurium revealed various regions of high similarity between these bacteria. Similarities at and near the 5′ and 3′ constant regions of the *S. flexneri* and *E. coli fliC* genes suggested the *fliC* gene from *S. flexneri* is an *E. coli* type gene, while similarity observed between the *fliC* gene of *S. sonnei* at the operator and 3′ constant region of *Salmonella* serotype Typhimurium and the downstream sequence of the *E. coli fliC* gene suggest the *S. sonnei* gene has undergone horizontal transfer and recombination (Tominaga et al., 1994). Coimbra et al. (2001) recently examined restriction fragment polymorphisms in the *fliC* genes of representative strains from each of the serotypes within the four species of *Shigella*. Seventeen F types, defined by *fliC* patterns sharing most of their bands, were observed among the 120 strains tested. Although O antigenic relationships between certain *E. coli* strains and shigellae are well documented, none of the F types observed among the tested *Shigella* strains matched the 62 F types previously described for *E. coli* (Machado et al., 2000). This method is a promising tool for the confirmation of atypical isolates as shigellae.

Prompted by reports that shigellae possessed the genes for flagella, Girón (1995) reexamined them for flagella by electron microscopy. He observed that strains of all four *Shigella* species, when cultivated under certain conditions, produced flagella. Motility was observed only by using low-concentration motility agar (0.175–0.2% agar), and genetic and environmental factors involved in the regulation of flagella are not yet identified. Expression of flagellated cells within a culture ranged from 1:300 to 1:1000, with flagellated cells typically producing one polar flagellum or occasionally 2–3 flagella in a semipolar topology. When expressed, the flagellum of *Shigella* is approximately 10 μm long and 12–14 nm in diameter and typically emanates from one pole of the bacterium. Putative flagellins of 33–38 kDa, which share immunologic similarities with *E. coli*, *Salmonella* spp., and *Proteus mirabilis* flagellins, have also been identified (Girón, 1995).

It should be emphasized, however, that shigellae are nonmotile under standard assay conditions. Al Mamun et al. (1997) showed that members of the four *Shigella* species became nonmotile by undergoing various kinds of stable mutations in different flagellar genes. Findings from these investigators suggest that the loss of flagella in *S. boydii* is attributable to a defect or deletion in the *fliF* operon, while the primary cause for nonmotility in *S. sonnei* is a deletion in the *fliD* gene. In *S. dysenteriae* and *S. flexneri*, IS1 insertions in the *flhD* master operon may be the primary cause of motility loss (Al Mamun et al., 1996).

Fimbrial adhesins In initial studies, *S. flexneri* was the only species of *Shigella* that was found to produce fimbriae (Duguid and Gillies, 1957). The fimbriae of *S. flexneri* were similar to those produced by *E. coli*; their width was uniformly about 0.01 μm and their length was between 0.3 and 2.0 μm. In these early studies, *S. flexneri* strains were found to readily undergo a reversible mutation between a fimbriate, hemagglutinating phase and a nonfimbriate, nonhemagglutinating phase. Findings by Snellings et al. (1997) confirmed the presence of fimbriae (type 1) on strains of *S. flexneri* and demonstrated their presence on recent clinical isolates of *S. boydii* and *S. dysenteriae*. Analysis of sequences upstream of the type 1 fimbriae subunit gene, *fimA*, showed that random phase variation between fimbriated and afimbriated states in *Shigella* was accompanied by the genomic rearrangement associated with phase variation in *E. coli* (Snellings et al., 1997). *Shigella* appears to switch between phases at a much lower frequency than *E. coli*, and this in combination with inappropriate growth conditions could partially explain the difficulty researchers have had demonstrating fimbriae in *Shigella*. The role fimbriae play in the pathogenesis of shigellae is not known. Some investigators have speculated that these structures may facilitate the formation of pellicles at the water–air interface in aquatic environments and thereby promote the survival of bacteria between outbreaks of disease (Snellings et al., 1997). Studies have also demonstrated the presence of type 3 and type 4 fimbrial adhesions and of afimbrial adhesions in *Shigella* strains (Qadri et al., 1989; Utsunomiya et al., 1992).

Another surface structure of note with respect to *Shigella* is the thin aggregative fimbria called curli. Curli have been demonstrated in a wide variety of *E. coli* and *Salmonella* spp. and are believed to mediate formation of biofilms or bacterial attachment to host intestinal cells. Rather than their presence, it is their complete absence from all four species of *Shigella*, as well as from enteroinvasive *E. coli* strains, that is notable here (Sakellaris et al., 2000). Shigellae are unable to produce curli because of insertions or deletions in the curli locus (*csg*); enteroinvasive *E. coli* strains are similarly affected or have another uncharacterized lesion(s) resulting in the lack of curli expression (Sakellaris et al., 2000). Since expression of curli occurs in a variety of *E. coli* strains, the widespread loss of curli from *Shigella* and enteroinvasive *E. coli* strains, which have a very similar mechanism of pathogenesis to *Shigella*, may represent a pathoadaptive mutation (Sakellaris et al., 2000). It is possible that during the divergence of *Shigella* from *E. coli*, the expression of curli in the new virulence niche was a selective disadvantage for *Shigella*.



Colonial or cultural characteristics On agar medium, colonies of *Shigella* strains can appear smooth and glistening or rough and dry. The degree of smoothness displayed depends in large part on the extent of polymerization of the O-antigen on the

S. sonnei			Sonne-Duval, Sonne III, Kruse E, *"S. ceylonensis"* A (Duval, 1904; Sonne, 1915)

[a]The serologic subdivision of serotypes is done for only *S. flexneri*. The roman numerals designate the "type" or serotype-specific antigen and the Arabic numerals designate group antigens that are shared among members of the different types. Different subserotypes are defined by the combination of group antigens they possess. Group antigens shown in parentheses may be expressed in varying amounts (undetectable to strongly positive) by members of certain subserotypes. For the reactions of *S. flexneri* in typing antisera see Ewing (1986c). For *S. flexneri* serotype 3, only two subserotypes are currently recognized; strains previously designated as subserotype 3c are now identified as subserotype 3b [III:(3,4), 6] (Petrovskaya and Khomenko, 1979; Brenner, 1984b).

lipopolysaccharide (LPS) molecule. For *S. sonnei*, colonies of freshly isolated strains with a smooth appearance are termed form I and are usually virulent. Form I colonies are genetically unstable and dissociate to rough-appearing colonies termed form II, which lack 2-amino-deoxy-L-altruonic acid from their LPS O-repeating unit (Kontrohr, 1977). This form variation in *S. sonnei* is associated with the loss of the 180–220 kilobase pairs (kbp) invasion plasmid. Colonial variation, which also correlates with the presence of the invasion plasmid, has been described for colonies growing on agar containing the dye Congo red. Smooth colonies that appear red on this agar are virulent, while colorless colonies are avirulent (Maurelli et al., 1984a). The dye interacts

FIGURE BXII.γ.209. Electron micrograph of (*A*) *S. dysenteriae* 1 strain A5468 and (*B*) *S. flexneri* 2a strain 3342-87 prepared by negatively staining in 0.5% uranyl acetate. Bar = 1000 nm. (Micrograph courtesy of Charles D. Humphrey, CDC.)

with outer membranes and outer membrane proteins, but not with lipopolysaccharides. Only smooth colonies are scored for virulence using this dye because rough colonies, which are avirulent, can nonspecifically bind the dye, presumably by exposure of non-virulence-associated outer membrane proteins.

Nutrition and growth conditions The shigellae are aerobes and facultative anaerobes. Their optimal growth temperature is about 37°C. They generally grow less rapidly than most strains of *E. coli* and other members of the family *Enterobacteriaceae*. The average interval between cell divisions of *S. dysenteriae* in milk was reported to be 23 min compared with 12.5 min for *E. coli* (Sinclair, 1972). Ahmed et al. (1988) studied the nutritional requirements of 375 clinical isolates from the four species of *Shigella* for growth in a minimal medium containing glucose, ammonium sulfate, and inorganic salts and observed that most isolates would not grow in this medium. They found that virtually all isolates that failed to grow in the minimal medium could grow if the medium was supplemented with methionine, nicotinic acid, and tryptophan. Methionine and tryptophan appeared to be an obligatory requirement for *S. dysenteriae* 1 strains, while the combination of nicotinic acid and tryptophan was required for *S. dysenteriae* 2 strains.

In contrast to *Salmonella*, *Shigella* species and certain isolates of *E. coli* are acid-resistant (Gordon and Small, 1993; Small et al., 1994). Stationary phase cells of *S. flexneri* have the ability to survive for several hours at pH 2.5, which is hypothesized to contribute to their low infective dose by allowing them to safely pass through the stomach before colonizing the intestinal tract. The ability to survive exposure to acid is a complex phenotype, which depends on growth phase, media, and possibly a variety of proteins located at different subcellular locations. At least three genes, *hdeA*, *rpoS*, and *gadC*, play a role in mediating the acid-resistance phenotype under various conditions (Waterman and Small, 1996).

Metabolism and metabolic pathways Like *E. coli*, shigellae are chemoorganotrophic and have both a respiratory and a fermentative type of metabolism. They are generally less metabolically active than typical *E. coli* strains. They produce pyruvate from the fermentation of glucose and other sugars and convert it primarily by mixed acid (formic acid) fermentation to formic acid, acetic acid, and ethanol. In contrast to *E. coli* strains, shigellae do not produce gas from the fermentation of sugars (anaerogenic), because they lack the complex hydrogenlyase system (formic hydrogenlyase) that splits formic acid into equal amounts of CO_2 and H_2. Exceptions include some strains of *S. flexneri* serotype 6 and *S. boydii* serotypes 13 and 14. In addition to the traits described above, members of the genus *Shigella* do not hydrolyze urea and do not produce detectable amounts of acetoin (acetyl methyl carbinol) or 2,3-butyleneglycol (Voges–Proskauer test negative). They also do not produce phenylalanine deaminase and do not produce acid from α-D-methylglucoside, erythritol, or esculin. They are uniformly negative for lysine decarboxylase. The pathogenic and evolutionary significance of this negative phenotype is addressed below in the pathogenicity section.

Shigella strains vary in their ability to metabolize glycerol. A study characterizing the glycerol dehydrogenase activity among *Shigella* species showed that the type of glycerol dehydrogenase produced could be used to help differentiate *Shigella* species from *E. coli* (Bouvet et al., 1995b). In this study, no strain of *Shigella*, with the exception of the Manchester biotype of *S. flexneri* serotype 6, was found to produce an NAD^+-linked glycerol dehydrogenase, glyDH-II, while the majority of *E. coli* strains contained this enzyme.

Genetics Extensive genetic homology between *Shigella* and *E. coli* has permitted the use of classical genetic techniques, such as conjugal transfer and integration of chromosomal material between *E. coli* and *Shigella* (Luria and Burrous, 1957; Falkow et al., 1963; Formal et al., 1970, 1971; Sansonetti et al., 1983) and the generation of R plasmids (Timmis et al., 1985), to construct maps of the *Shigella* chromosome based on the known map for *E. coli* K-12. A *Not*I restriction map of the chromosome of *S. flexneri* 2a, with the assignment of nine virulence-associated loci identified by Tn5 insertions, was constructed by Okada et al. (1991). Genes that play a role in pathogenesis have received extensive study and were reviewed by Parsot and Sansonetti (1996), and are highlighted below in the pathogenicity section. Genes involved in O-antigen synthesis have also received considerable attention and are reviewed by Brahmbhatt et al. (1992) and discussed below in the antigenic structure section.

The work of Brenner et al. (1972a, 1973a) clearly established the genetic basis for the close biochemical and serologic relatedness between *E. coli* and *Shigella* that had been appreciated for many years. Their findings from DNA reassociation reactions followed by thermal elution chromatography on hydroxyapatite showed that, with the exception of *S. boydii* 13 strains, strains of

Shigella from all four species were as related to each other (sharing 80% or more of their nucleotide sequences) as they were to strains of *E. coli* (Brenner et al., 1973a). Estimates of genome size by I-*Ceu*I macrorestriction analysis revealed that the chromosome sizes of all four *Shigella* species were in a similar range to those observed for *E. coli* (Shu et al., 2000). By this analysis, the genome sizes for the type strains of the four species of *Shigella* were 4.415×10^6 bp for *S. dysenteriae*, 4.792×10^6 bp for *S. flexneri*, 4.645×10^6 bp for *S. boydii*, and 4.501×10^6 bp for *S. sonnei*, while those for *E. coli* were 4.653×10^6 bp and 4.816×10^6 bp for two *E. coli* strains (Shu et al., 2000). The genome sequences of two different isolates of *S. flexneri* 2a have been published and are deposited in GenBank under accession numbers AE014073 and AE005674 (Jin et al. (2002); Wei et al., 2003).

Published ribosomal RNA sequences for the four species of *Shigella* and of *E. coli* are nearly identical, with more than 99% homology (Shu et al., 2000). Like *E. coli*, *Shigella* strains have seven ribosomal RNA operons as determined by restriction analysis with I-*Ceu*I, an enzyme that specifically cuts a 26-bp site in the 23S rDNA sequence in *rrn* operons (Shu et al., 2000). The mapping of seven *E. coli* genes, each known to reside on a different I-*Ceu*I fragment in *E. coli* K-12, revealed that some chromosomal rearrangements involving the fragments corresponding to fragments D and E of *E. coli* K-12 took place in *S. dysenteriae* and *S. flexneri*. Available findings did not permit a determination of the mechanism (translocation versus inversion of fragments) for these rearrangements. Hybridization patterns of *S. boydii* and *S. sonnei* strains were similar to those observed for *E. coli* strains, while the patterns for the *S. dysenteriae* and *S. flexneri* strains were each distinct.

Shigellae can carry a variety of insertion sequences (IS elements) including IS*1* (Nyman et al., 1981; Kharat and Mahadevan, 2000); iso-IS*1* (Ohtsubo et al., 1981); IS *2* (Soldati and Piffaretti, 1991); IS*5* (Schoner and Schoner, 1981); IS*200* (Gibert et al., 1990); IS *630* (Houng and Venkatesan, 1998); and IS*911* (Prere et al., 1990). IS elements comprise over 6% of the sequenced genome of *S. flexneri* 2a; 314 IS elements were identified in strain 301 and 284 IS elements in strain 2457T (Jin et al. (2002); Wei et al., 2003). Some of these, such as IS *1* and iso-IS*1*, are present in large numbers in the chromosome of *Shigella* (50 to >150 copies per chromosome, respectively) and have been associated with negative phenotypes. For example, the inability of *S. sonnei* to utilize the β-glucoside salicin has been shown to involve the insertional inactivation of the gene *bglB*, encoding phospho-β-glucosidase B, by a novel IS (Kharat and Mahadevan, 2000). In contrast to adverse effects of IS elements on some genes, the IS *630* element appears to be required for the stable expression of form I antigen in *S. sonnei* (Houng and Venkatesan, 1998).

Plasmids, phages and phage typing, bacteriocins Shigellae carry a variety of plasmids. The most notable is the large (180–220 kbp) invasion plasmid, which belongs to the RepFIIA family of replicons (Silva et al., 1988) and is present in all virulent strains of *Shigella*. This plasmid carries genes that play an essential role in these organisms' ability to cause invasive disease and appears to contain regions from different origins (mol% G + C values ranging from 30% for *virF* to 49% for *sepA*). The complete DNA sequence of the virulence plasmid of *S. flexneri* has been determined (Buchrieser et al., 2000; Venkatesan et al., 2001). The organization and origin of the genes encoded on the plasmid are discussed in these articles. In some serotypes, plasmids carry genes involved in synthesis of the O antigen (Kopecko et al., 1980; Watanabe and Timmis, 1984). Antibiotic resistance plasmids are also common among the shigellae. Because of the variety of plasmids carried by *Shigella*, plasmid profile analysis has been used widely to discriminate between strains during outbreak investigations. The use of this technique has declined in recent years in favor of molecular methods that examine differences in total cellular DNA and are less influenced by environmental or host pressures that can result in loss or acquisition of plasmids.

Shigellae have also been reported to carry Hsd (host specificity for DNA) plasmids. Strains of *S. flexneri* and *S. sonnei* carrying plasmid-encoded isoschizomers of either *Eco*RII or *Nci*I (Lee et al., 1997) and a strain of *S. boydii* serotype 13 carrying a plasmid-encoded isoschizomer of *Nru*I (Mise et al., 1986) have been described.

Shigellae are susceptible to a variety of bacteriophages, and this property has permitted the development of several phage typing systems (Thomen and Frobisher, 1945; Hammarström, 1947, 1949; Slopek et al., 1968, 1973; Lazlo et al., 1973; Pruneda and Farmer, 1977). A detailed description of the methods and the different bacteriophages used for typing *Shigella* was reported by Bergan (1979). Systems described to date, which typically use a panel of 10–20 bacteriophages to detect different patterns of lysis on a test strain, have focused on discriminating between strains within a serogroup or serotype. Discrimination between strains is generally good; for example, the method described by Lazlo et al. (1973) identified 90 types among more that 4000 strains of *S. flexneri* tested, and that of Pruneda and Farmer (1977) discriminated 87 different types among 265 strains of *S. sonnei*. Control of assay conditions, particularly the media and the smoothness of the cultures, is important for obtaining reproducible results. While the majority of strains can be characterized by phage typing, common phage types exist and it may be necessary to apply additional typing methods to achieve adequate discrimination.

Genes carried by some bacteriophages in shigellae have been identified. Among the serotypes of *S. flexneri*, bacteriophages have been demonstrated to carry genes, such as acetyltransferase, glucosyltransferase, or novel O-antigen polymerase genes, that play a role in determining the type and group determinants of the O antigens (Gemski et al., 1975; Lindberg et al., 1978; Clark et al., 1991a; Huan et al., 1997a, b; Mavris et al., 1997; Guan et al., 1999). Because many bacteriophages use O-antigenic polysaccharide chains as receptors for adsorption and infection, the modification of the host bacterial O antigens by the incoming phages is hypothesized to be a protective mechanism for excluding homologous phages from entering and may also help lysogenized cells evade preexisting host immunity.

Findings reported by McDonough and Butterton (1999) provide evidence, in the sequences surrounding the Shiga toxin gene, suggesting that *S. dysenteriae* 1 was once lysogenized by a Shiga toxin-encoding lambdoid prophage, which became defective as a result of deletions after IS element insertions and rearrangements. These authors also provided evidence that Shiga toxin-encoding phages from *E. coli* can be stably introduced into *Shigella*. Other than *S. dysenteriae* 1, Shiga toxin-producing strains of *Shigella* are extremely rare.

Antigenic structure The different serotypes are distinguished by antigenic determinants that reside in the O antigen, which is part of the LPS molecule. The LPS molecule consists of three

parts: lipid A, which is made up of sugars and fatty acids and anchors the LPS molecule in the outer membrane; the core, which is made up of a single sequence of heptoses and hexoses and links the lipid A to the O antigen; and the O-antigen chain, which is composed of a repetitive sequence of hexoses and extends from the surface of the bacterium. The genetics of O antigen biosynthesis have been extensively studied and are reviewed by Schnaitman and Klena (1993) and Whitfield (1995). O antigens may contain from 10 to as many as 30 repeats of an oligosaccharide unit (O unit) each composed of three to six sugars. The diversity of O antigens is a result of varying combinations of sugars in the O unit, the type of chemical linkages between them, and the presence of nonsugar moieties such as O-acetyl residues or amino acids. Six to nineteen genes may be involved in the synthesis of the O antigen, and these are typically located together on the chromosome in a region (10 kbp or greater) called the *rfb* cluster. Depending on the sugars making up the O unit, serotypes may have completely different sets of genes. For certain shigellae, such as *S. dysenteriae* 1, *S. sonnei*, and *S. flexneri* 1–5, one or more genes for the synthesis of the O unit are carried on plasmids or lysogenic bacteriophages. Like *E. coli* and other Gram-negative bacteria, *Shigella* have a conserved 39-bp sequence, designated JUMPstart for "just upstream of many polysaccharide-associated gene starts," located in the noncoding region upstream of the *rfb* cluster (Hobbs and Reeves, 1994). This region has been used to develop a molecular method for serotyping *Shigella* isolates (Coimbra et al., 1999).

The O antigens of most serotypes of *Shigella* are identical or partially related to the O antigens of *E. coli* (Ewing, 1953, 1986c). At least 13 identical and numerous reciprocal serologic relationships exist between *Shigella* and *E. coli* (Ewing, 1986c).

With the acceptance of provisional serotypes E22383 and E23507 as new serotypes (Ansaruzzaman et al., 1995), *S. dysenteriae* contains 15 serotypes, each with a distinctive antigen by which it can be recognized; there are few cross-reactions, either within the species or with other species that present difficulties for serotyping strains. Of the different serotypes within this species, the O antigen of *S. dysenteriae* 1 has been the most extensively studied because of efforts to develop LPS-based antidysentery vaccines. Genes involved in the synthesis of its O antigen have been identified, and their structure and function were reviewed by Schnaitman and Klena (1993). Eight of these genes are located together in the chromosome and two genes (*rfp* and *rfe*) lie outside the chromosomal cluster; *rfp* is carried on a 9-kbp multicopy plasmid.

S. flexneri contains eight serotypes and nine subserotypes. The serotypes are antigenically related, but each has a qualitatively distinct major (type) antigen; the group antigens are shared by other members of the species. Because of the important intragroup relations, highly absorbed sera are needed for the detailed serotyping of *S. flexneri*. The immunochemical and genetic bases of the complex antigenic structures of the species have been summarized by Petrovskaya and Bondarenko (1977). The O antigens of all serotypes, except *S. flexneri* 6, contain group antigens 3, 4 as a main primary structure. The type-specific antigens I, II, IV, and V and the group antigens 7, 8 are all the result of phage conversion of the 3, 4 antigens resulting in the incorporation of α-glycosyl and/or glucosyl groups to the common O-repeating unit of the LPS molecule. Type-specific antigen III and group antigen 6 differ from the above antigens in that they contain acetyl groups. Nevertheless, these antigens are also formed as a result of phage conversion of the 3, 4 antigens. The genes involved in synthesis of the common O-repeating unit are located on the chromosome in the *rfb* cluster.

The classification of *S. flexneri* 6 as a serotype of *S. flexneri* was questioned by Petrovskaya and Bondarenko (1977), who proposed that it be transferred to *S. boydii* because the immunochemical structure and genetics of its O antigen were more consistent with those found among serotypes of *S. boydii* than among serotypes 1-5, Y and X of *S. flexneri*. In 1984, the International Committee on Systematic Bacteriology Subcommittee on the Taxonomy of *Enterobacteriaceae* considered this proposal and upheld the 1973 recommendation of the Subcommittee Working Group on *Shigella* to reject reclassification of *S. flexneri* 6 as a serotype of *S. boydii* on the grounds that it would have no practical value and would cause confusion by altering a well-accepted classification system (Brenner, 1984b).

S. boydii contains 19 serotypes and each has a qualitatively distinct antigen; there may be some cross-reactions with antisera to other *Shigella* species, but these seldom interfere with diagnosis. Serotypes 10 and 11 share a major antigen, although each possesses a specific antigen.

S. sonnei contains only one serotype but may exist in one of two forms or "phases": form I (smooth colonial appearance) and form II (rough colonial appearance). Each form has a distinctive antigen, and antiserum containing agglutinins for both phases should be used for identification. Form I cells, which are virulent and carry the 180-kbp invasion plasmid, are typically isolated from acutely ill individuals. These cells can rapidly and irreversibly switch to form II cells, which are avirulent, when the invasion plasmid is lost. Form II cells may be isolated from ill individuals; however, they are more frequently isolated from individuals during convalescence and toward the end of an outbreak.

The O antigen unit of form I cells is structurally unique compared with those from other shigellae or *E. coli*, and it is chemically identical to that found in serotype 17 of *Plesiomonas shigelloides* (Rauss et al., 1970; Kenne et al., 1980). With the exception of two (*wzz* and *wbg*), the genes responsible for expression of the form I O antigen are located on the invasion plasmid and are nearly identical to those present in *P. shigelloides* (Shepherd et al., 2000). Factors influencing the loss of the plasmid carrying these genes are not well understood; however, Houng and Venkatesan (1998) propose that an insertion element present in the plasmid may be necessary for the stable expression of the form I antigen. These authors discovered the insertion element IS *630* within the O antigen gene cluster of all virulent strains of *S. sonnei* and observed that recombinant strains of *E. coli* carrying the cloned *S. sonnei* O antigen genes could stably express the form I antigen only when the IS *630* element was present.

While the form I O antigen expressed by *S. sonnei* is encoded by the plasmid-borne O antigen genes from *P. shigelloides* (Shepherd et al., 2000), findings by Lai et al. (1998) show that *S. sonnei* once had a typical chromosomal O antigen gene cluster. The remnant O antigen gene cluster apparently arose from a deletion due to homologous recombination between *manB* genes present in the adjacent O antigen and colanic acid gene clusters. The remnant chromosomal O antigen genes are not functional.

In addition to the recognized serotypes of shigellae, a number of provisional *Shigella* serotypes have been described. These may be added to the serotyping schema in the future, but in the meantime they remain *sub judice*, and antisera for their identification are usually available only at a very few reference laboratories. Provisional serotypes under consideration at present include serotypes E670/74 (Gross et al., 1989), 3162-96 (Kuijper

et al., 1997), 93-119 (Matsushita et al., 1997), 96-204 (Matsushita et al., 1998), and 96-265 (Frank Rogers, National Laboratory for Enteric Pathogens, Health Canada, Winnipeg, Canada; personal communication), which are biochemically consistent with members of subgroup A; serotypes Y394 (Wehler and Carlin, 1988), 88-893 (Matsushita et al., 1992a), 89-141 (Matsushita et al., 1992b), which are biochemically and antigenically consistent with members of subgroup B; and serotypes 1621-54 (Ewing et al., 1958), E28938 (Gross et al., 1989), and 99-4528 (Frank Rogers, National Laboratory for Enteric Pathogens, Health Canada, Winnipeg, Canada; personal communication), which are biochemically consistent with members of subgroup C.

Pathogenicity Shigellae are pathogens of humans and other primates. Although there have been occasional reports of infections in dogs, other animals are resistant to infection. Laboratory animals such as mice, rabbits, and guinea pigs may be infected orally but only following starvation and treatment with gastric antacids and antiperistaltic agents.

Shigellosis (bacillary dysentery) is transmitted orally through contaminated food and water or by direct fecal-oral spread. A review of the literature estimated the annual number of cases throughout the world to be 164.7 million, of which 163.2 million were in developing countries (with 1.1 million deaths). A total of 69% of all episodes and 61% of all deaths attributable to shigellosis involved children less than 5 years of age (Kotloff et al., 1999). Studies of volunteers have demonstrated that ingestion of as few as 200 organisms is sufficient to cause dysentery (DuPont et al., 1989). The incubation period is from 1 to 7 days with symptoms commonly manifesting on day 3. Shigellosis often (but not always) begins with a watery diarrhea that precedes the characteristic dysentery symptoms. The diarrhea phase probably results from production of enterotoxins by the bacteria as they transit through the small intestine.

The lesions of bacillary dysentery are usually restricted to the rectum and large intestine, but in severe cases part of the terminal ileum may be affected. *Shigella* penetrates into the epithelial cells lining the colon, multiplies within these cells, and spreads from cell to cell through the mucosa. The foci of infected cells coalesce to form abscesses. Small volume bloody and mucoid stools contain dead cells along with mucus and large numbers of bacteria. Typically there is acute inflammation with ulceration of the epithelium, and the presence of polymorphonuclear leukocytes in the stools is consistent with the inflammatory nature of shigellosis. Common clinical signs include fever, severe abdominal pain, and cramping. The most severe forms of shigellosis are caused by strains of *S. dysenteriae* 1, which also produces a potent cytotoxin (Shiga toxin) that has been shown to play a role in the severity of the illness it causes (Fontaine et al., 1988). Shiga toxin-producing strains can cause hemolytic uremic syndrome. *S. sonnei* strains cause milder forms of the disease, while *S. flexneri* and *S. boydii* strains can cause either severe or mild illness. Bacillary dysentery is a self-limiting disease. The organisms rarely spread deeper than the lamina propria, and bloodstream involvement is uncommon.

Treatment of shigellosis with appropriate antimicrobial therapy results in decreased duration of both symptoms and excretion of the organism (Haltalin et al., 1967; Salam and Bennish, 1991); however, empirical antimicrobial therapy for this illness has become complicated by the increasing incidence of multiple drug resistance among *Shigella* strains. Of historical note, the first observation of multiple, transferable drug resistance in bacteria was in *Shigella* in Japan (Ochiai et al., 1959). Over the years, *Shigella* species have become increasingly resistant to most of the widely used antibiotics (Bennish et al., 1992). Multiple antibiotic resistance in *S. dysenteriae* 1 is so widespread that it is uniformly susceptible only to the fluoroquinolones (Sack et al., 1997). Antimicrobial resistance surveys of *Shigella* species conducted during the 1990s in developed and developing countries showed that multiple drug resistance exists in strains of all species (Keusch and Bennish, 1998; Mates et al., 2000; Replogle et al., 2000). The resistance patterns varied by species and by country, highlighting the need for monitoring of local antimicrobial resistance patterns to develop appropriate empirical therapy. Because *Shigella* infections are typically self-limiting and because antibiotic resistance frequently develops after treatment, some have proposed that antimicrobial therapy be reserved for the most severely ill patients, immunocompromised patients, and patients for whom eliminating carriage is a public health priority (Weissman et al., 1973; Replogle et al., 2000). Others feel that, because the infection is generally transmitted from person to person and the infected person represents the major reservoir of infection, each patient with a positive stool culture or with known bacillary dysentery should be treated to prevent the spread of infection (Dupont, 2000).

The hallmarks of *Shigella* pathogenicity are induction of diarrhea, the ability to invade eucaryotic cells, multiplication inside these cells, and spread from cell to cell. The rabbit ileal loop assay has been used as an experimental model to demonstrate production of at least two different enterotoxins by *S. flexneri*, which may play a role in the diarrhea caused by the organism (Fasano et al., 1995; Nataro et al., 1995). The invasive properties of *Shigella* have been demonstrated in experimental infection of monkeys (LaBrec et al., 1964) as well as in the Serény test, which measures the ability of the bacteria to invade and produce keratoconjunctivitis in the guinea pig eye (Sérèny, 1957). Invasion can also be demonstrated in mammalian cells in tissue culture (LaBrec et al., 1964; Ogawa et al., 1967; Day et al., 1981). The ability of the bacteria to spread from cell to cell after invasion is measured by the plaque assay (Oaks et al., 1985). While shigellae are killed after being taken up by polymorphonuclear leukocytes (Mandic-Mulec et al., 1997), they induce apoptosis in macrophages and kill these cells after uptake (Zychlinsky et al., 1992). *S. dysenteriae* serotype 1 produces Shiga toxin, a potent inhibitor of eucaryotic protein synthesis (O'Brien et al., 1992). Shiga-like toxins are also produced by enterohemorrhagic strains of *E. coli* (O'Brien et al., 1984).

Shigella strains invade the intestinal mucosal surface via a pathogen-directed phagocytic process that actively involves elements of the host cytoskeleton (Tran Van Nhieu et al., 2000). Unlike most other intracellular bacterial pathogens, however, *Shigella* strains rapidly lyse the endocytic vacuole upon entry and are released free into the host cell cytoplasm where they replicate. Shigellae are actively motile during growth inside the host cell. This motility is unusual in that it is not driven by bacterial-based flagella. Rather a bacterial protein, expressed in the outer membrane at one pole of the bacterium, catalyzes the polymerization of host cell actin filaments (Makino et al., 1986; Bernardini et al., 1989). Formation of actin tracks literally propels the bacterium through the cytoplasm as actin monomers polymerize into long filaments from one pole of the bacterium. This motility is required for cell-to-cell spread of *Shigella*. Mutant strains of *Shigella* that fail to display this intracellular motility produce a greatly attenuated form of disease in the monkey model, thus confirm-

ing this phenotype as a critical hallmark of *Shigella* pathogenesis (Sansonetti et al., 1991).

Virulence in *Shigella* spp. is dependent on expression of a group of genes encoded on a large plasmid. The role of this plasmid in *Shigella* virulence was first demonstrated in *S. flexneri* and *S. sonnei* (Sansonetti et al., 1981, 1982). Subsequently, all virulent species of *Shigella* and enteroinvasive strains of *E. coli* were shown to carry a 180–220-kbp plasmid that shares substantial DNA homology with these prototype virulence plasmids (Sansonetti et al., 1985). Introduction of these plasmids into plasmid-cured strains of *Shigella* or laboratory strains of *E. coli* K-12 imparts on the bacteria the ability to invade mammalian cells in tissue culture. Thus, the *Shigella* virulence plasmid encodes all the genes required for the invasive phenotype of *Shigella*. The DNA sequence of the virulence plasmid of *S. flexneri* 5a has been determined and deposited in GenBank under accession numbers AF348706, AL391753, and AF386526 (Buchrieser et al., 2000; Venkatesan et al., 2001; Jin et al. (2002)).

A 37-kbp region of the plasmid contains the minimal sequence needed for invasion (Maurelli et al., 1985; Baudry et al., 1987). The genes in this region are roughly grouped into two clusters transcribed from opposite strands. They encode the Ipa proteins, required for inducing uptake of the bacteria by mammalian cells, and Mxi/Spa proteins of a dedicated type III secretion apparatus for transport of the Ipa proteins outside the bacteria. Type III secretion systems are specialized transport systems found in animal and plant pathogens and are responsible for mediating interactions between the bacterial pathogen and its eucaryotic host (Cornelis and Van Gijsegem, 2000). The Mxi and Spa proteins of the Shigella type III secretion system show strong homologies with the analogous proteins of the type III secretion systems of *Salmonella* Typhimurium, enteropathogenic and enterohemorrhagic *E. coli*, and *Yersinia* spp. The *Shigella ipa* genes (*ipaBCDA*) encode the secreted effector molecules that mediate the bacteria-induced phagocytic (invasion) event. The Ipa proteins (invasion plasmid antigens) are the immunodominant antigens recognized by convalescent-phase sera from shigellosis patients and challenged monkeys (Maurelli et al., 1985; Oaks et al., 1986). Unlike the genes of the virulence plasmid that are involved in invasion and postinvasion steps, the chromosomal genes associated with virulence of *Shigella* appear to mostly encode modulators of pathogenicity.

Of interest from the point of view of bacterial evolution and pathogenesis are the genes that are present in nonpathogenic strains of *E. coli* but are missing from the chromosome of *Shigella*. A cryptic prophage in the *E. coli* K-12 chromosome that is missing in shigellae encodes an outer membrane protease, OmpT. When the *ompT* gene is introduced into *Shigella* by conjugation, the strain remains invasive but loses the ability to spread from cell to cell. This phenotype is due to OmpT protease degradation of IcsA, the bacterial protein responsible for actin polymerization and motility (Nakata et al., 1993). Another example of a missing genetic locus in the *Shigella* genome is *cadA*, the gene for lysine decarboxylase. Although lysine decarboxylase activity is present in >85% of *E. coli* strains, it is absent in all strains of *Shigella* spp. and enteroinvasive *E. coli*. When *cadA* is reintroduced into *S. flexneri*, the decarboxylation of lysine generates cadaverine. The *Shigella* enterotoxins are inhibited by cadaverine (Maurelli et al., 1998). Thus, these genes can be considered antivirulence genes and the missing genetic locus, a black hole. The example of *Shigella* illustrates another way that pathogens evolve from their nonpathogenic commensal relatives by both acquiring genes (e.g., the virulence plasmid) that contribute to virulence and deleting genes that are incompatible with expression of these new virulence traits.

Growth temperature is the critical stimulus for regulation of virulence in *Shigella*. Wild-type *Shigella* strains grown at 37°C display all the attributes of virulence, whereas the same strains grown at 30°C are avirulent in the Serény test and fail to invade tissue culture cells (Maurelli et al., 1984b). The loss of virulence is reversible and the organisms regain full virulence (invasion and ability to provoke keratoconjunctivitis) after the growth temperature is shifted to 37°C. Paradoxically, growth of *Shigella* at 37°C in the laboratory leads to spontaneous deletion or loss of the virulence plasmid. Evidence suggests that expression of virulence genes *in vitro* is not well tolerated by the bacteria and leads to selection of variants that no longer express these genes either due to mutations in regulatory genes or deletion of plasmid sequences (Schuch and Maurelli, 1997). Strains grown at 30°C retain the virulence plasmid intact.

Despite many years of effort, an effective vaccine against shigellosis still has not been developed. Formulations have included killed whole cells, live attenuated strains, subunit vaccines (conjugate and proteosome), and ribosomal vaccines. The World Health Organization has placed *Shigella* vaccine development on its list of priorities for the Global Program for Vaccines and Immunization (WHO, 1997).

Ecology Shigellae are host-adapted to humans and subhuman primates, where they typically inhabit the intestinal tract. *Shigella* infections in captive primates are not uncommon; however, two groups of investigators (Takasaka et al., 1964; Carpenter and Cooke, 1965) found no evidence that wild primates living without human contact are infected. During the acute stage of the illness, shigellae are typically shed in large numbers in the feces. The number of organisms dramatically declines during recovery, and in some individuals a carrier state may develop in which organisms may persist in the feces for several weeks after the symptoms have subsided. The spread of *Shigella* infection is typically from person to person by fecal–oral transmission or from contaminated food or water. In situations without good sewage disposal and poor hygiene conditions, flies may act as vectors (Levine and Levine, 1991).

Enrichment and Isolation Procedures

Food and water The minimum infecting dose of shigellae is small (10–100 organisms), and occurrence of the organisms in food, milk, and water may be significant even when only a small number of organisms are present. There are no reliable and effective enrichment methods, however, and the true incidence of *Shigella* contamination of foodstuffs cannot be accurately determined. The GN (Gram-negative) broth of Hajna (1955) may be useful for enrichment of *Shigella*, and it is recommended that the investigation of foodstuffs include an enrichment step using this medium. Subsequent steps in the isolation of *Shigella* from foods should follow the procedure recommended for fecal specimens.

Fecal specimens Freshly passed stools should be examined, although, if this is not possible, fecal swabs or rectal swabs showing marked fecal staining may be used. The specimens should be collected during the acute stage of the disease and before any chemotherapy is started. Specimens should be examined as soon after collection as possible. If the specimen includes blood and mucus, these should be included in the portion examined.

Although GN broth and Selenite broth are commonly used, no enrichment medium for *Shigella* consistently improves the

recovery rate beyond that obtained by direct plating alone. Because some strains of *Shigella* grow poorly on inhibitory media, both a relatively noninhibitory selective medium (e.g., MacConkey) and an inhibitory medium (e.g., xylose desoxycholate, deoxycholate citrate agar, or Hektoen enteric agar) should be used for isolation. Salmonella–Shigella (SS) agar is not recommended because it inhibits the growth of some strains of *S. dysenteriae* 1. Instructions for preparation of these media are given by Ewing (1986d) and Atlas (1997). Specimens are streaked onto the chosen media, and after overnight incubation at 35–37°C, lactose- or xylose-nonfermenting colonies are selected for further examination. Even when stool specimens from acute dysentery are examined, there may be only a scanty growth of *Shigella*. Suspicious colonies should be tested by biochemical and serologic methods (direct slide agglutination or coagglutination of antibody-coated latex beads) to confirm the identification of shigellae. For *S. flexneri*, which is the most difficult to prepare typing antisera against because of its shared group antigens, a panel of monoclonal antibodies has been developed for typing (Carlin et al., 1989). In some reference laboratories, molecular methods, such as DNA hybridization (Boileau et al., 1984), PCR (Frankel et al., 1990; Sethabutr et al., 1993; Yavzori et al., 1994; Houng et al., 1997; Villalobo and Torres, 1998; Sethabutr et al., 2000), enzyme-linked immunosorbent assays (Floderus et al., 1995; Pal et al., 1997), and immunomagnetic capture assays (Islam et al., 1993), targeting O antigens or invasion-associated genes/proteins are being used to detect shigellae and enteroinvasive *E. coli*.

Laboratory surveillance for *Shigella* infections is conducted in many countries and has been valuable for investigating outbreaks of shigellosis and for guiding vaccine development efforts. Serotyping has been and continues to be the primary method for discriminating between strains. During outbreaks or for highly prevalent serotypes such as *S. sonnei*, isolates are often subjected to a variety of additional phenotypic or molecular typing methods. Virtually all the secondary typing methods are predicated upon knowledge of the isolate's serotype. Other methods commonly used for differentiating between *Shigella* strains include colicin typing and phage typing. The colicin typing scheme for *S. sonnei* described by Abbot and Shannon (1958) has been used widely and distinguishes 14 types using 15 indicator strains (see Procedures for Testing Special Characters). Phage-typing schemes have also been used by many investigators. While a number of schemes have been described for *S. flexneri* and *S. sonnei*, only a few have been reported for *S. dysenteriae* and *S. boydii* (reviewed by Bergan, 1979). A variety of molecular subtyping methods have been applied to *Shigella*, which include ribotyping (Hinojosa-Ahumada et al., 1991; Faruque et al., 1992; Nastasi et al., 1993), IS element typing (Soldati and Piffaretti, 1991), enterobacterial repetitive intergenic consensus (ERIC) sequence-based PCR (Liu et al., 1995a), randomly amplified polymorphic DNA (Bando et al., 1998), and macrorestriction endonuclease analysis with pulsed-field gel electrophoresis (PFGE) (Soldati and Piffaretti, 1991; Liu et al., 1995a; Litwin et al., 1997). Because of its discriminatory potential, PFGE is the method preferred by many investigators for molecular subtyping studies, particularly for epidemiologic investigations of *S. sonnei* infections. This method proved invaluable in the investigation of a protracted outbreak of *S. sonnei* infections among members of traditionally observant Jewish communities in North America (Sobel et al., 1998) and was critical in an investigation of geographically unrelated cases of *S. sonnei* infection, identifying parsley from a single farm as the vehicle of infection (Centers for Disease Control, 1999).

Maintenance Procedures

Shigella cultures are maintained best frozen in liquid nitrogen. Liquid culture medium, such as trypticase soy broth, containing 10–20% glycerol is commonly used as a freezing medium. Cultures of *Shigella* may also be lyophilized or maintained on blood agar base or Dorset egg medium (stabbed slants or deeps) at room temperature; however, rough and degraded variants frequently arise under these conditions.

Procedures for Testing Special Characters

For colicin typing of *S. sonnei*, the organism under investigation is inoculated heavily in a broad streak across a blood agar plate and incubated at 37°C for 24 h. The bacterial growth is then removed from the agar by scraping with a glass slide, and the organisms remaining are killed with chloroform. The 15 indicator strains are streaked onto the plate at right angles to the original line of growth. After further incubation for 8–12 h, the patterns of inhibition of growth of the indicator strains can be examined and compared with a key. It is important that controls be included in every batch of tests.

Differentiation of the genus *Shigella* from other genera

The biochemical identification of *Shigella* is complicated by the similarity of some strains of other genera. In particular, strains of *Hafnia alvei*, *Providencia* spp., *Aeromonas* spp., and atypical *E. coli* can cause difficulties. Advances in our knowledge of the genetics of microorganisms have allowed the development of new approaches for identifying and detecting bacteria. Molecular strategies have been developed to facilitate microbial identification. Spierings et al. (1993) described a PCR assay targeting DNA sequences that encode the hypervariable surface-exposed regions of the outer membrane protein PhoE, which shows a high degree of species specificity and can differentiate strains of *Shigella* and *E. coli* from strains of other enteric bacteria.

Nonlactose-fermenting or anaerogenic strains of *E. coli* are commonly quite difficult to differentiate from shigellae. Of particular interest are members of the so-called Alkalescens Dispar (A-D) group, which contains nonmotile, anaerogenic biotypes of *E. coli*. These are best differentiated from *Shigella* by means of the Christensen's citrate and lysine decarboxylase tests, in which *Shigella* is always negative. The members of the A-D group were divided into eight serogroups based on their O antigens (Frantzen, 1950), although most of these are identical with or closely related to *E. coli* antigens.

Taxonomic Comments

The genus *Shigella* consists of nonmotile organisms that conform to the definition of the family *Enterobacteriaceae* and have the biochemical and antigenic properties described above. Circumscription of the genus is problematic because of the close genetic relationship that exists between *Shigella* spp. and *E. coli*. There are no unique traits exclusively associated with *Shigella*. The negative phenotypes identified with *Shigella* spp. can occur in *E. coli*, particularly among the nonmotile, anaerogenic biotypes of *E. coli*, while positive phenotypes seen among typical *E. coli* isolates, such as lactose or sucrose fermentation and gas production from the fermentation of glucose, can occasionally occur in *Shigella*. Some *E. coli* strains (enteroinvasive *E. coli*) can also cause a dysentery-like illness, which is mediated by similar plasmid-encoded virulence genes as those possessed by *Shigella*.

Although pathogenicity (i.e., the ability to cause dysentery)

was not endorsed by the *Enterobacteriaceae* Subcommittee of the International Committee on Bacteriological Nomenclature for the classification of *Enterobacteriaceae* (Carpenter, 1963), it has influenced and continues to influence the classification of *Shigella* by virtue of the fact that only strains that are capable of causing dysentery receive consideration for addition to this group. Strains that do not cause dysentery but yield biochemical reactions consistent with those produced by *Shigella* are not considered for inclusion in this genus. The preservation of this association between bacteria classified as *Shigella* and a distinct form of diarrheal illness (dysentery) has sustained a functionally useful nomenclature that might otherwise have yielded over the years to persuasive findings that reveal a sufficiently close relationship between *Shigella* and *E. coli* to consider them the same species (Brenner et al., 1972a, 1973a).

The names adopted by Pupo et al. (2000), (*Escherichia coli* clone Dysenteriae, *Escherichia coli* clone Flexneri, *Escherichia coli* clone Boydii, and *Escherichia coli* clone Sonnei), reflect the well-documented natural relationships that exist between *Shigella* and *E. coli* and have merit from a phylogenetic perspective; however, their widespread adoption will happen only when it is important to users to communicate these relationships through the bacterial names. Until that time, the medically useful link between the genus epithet *Shigella* and shigellosis, the term for the disease caused by these bacteria, will sustain the current nomenclature.

Findings from numerous studies raise questions about the inclusion of *S. boydii* 13 strains in the genus *Shigella*. The DNA–DNA reassociation findings reported by Brenner et al. (1982c) show that *S. boydii* 13 strains were related to each other, but clearly separable from other *Shigella* and *E. coli* (average 65% relatedness). Findings from MLEE (Ochman et al., 1983; Pupo et al., 1997), nucleotide sequence analysis of housekeeping genes (Pupo et al., 2000), ribotyping (Rolland et al., 1998), and esterase electrophoretic polymorphisms (Goullet and Picard, 1987) also show a distant relationship between *S. boydii* 13 strains and other shigellae.

Differentiation of the species of the genus *Shigella*

Biochemical characteristics useful for differentiating the species of *Shigella* are listed in Table BXII.γ.275.

List of species of the genus Shigella

1. **Shigella dysenteriae** (Shiga 1898) Castellani and Chalmers 1919, 935, Epit. Spec. Cons. Opinion 11 of the Jud. Comm. 1954a, 149[AL] (*Bacillus dysenteriae* Shiga 1898, 817.)*
dys.en.te′ri.ae. Gr. n. *dysenteria* dysentery; M.L. gen. n. *dysenteriae* of dysentery.

Colonies of serotype 1 often have a pinkish tinge on Leifson's deoxycholate citrate agar. Catalase is not produced by serotype 1, but is usually produced by strains of other serotypes. D-mannitol is not fermented. Dulcitol is fermented by strains of serotype 5. Gas from the fermentation of sugars is not produced. Indole is not produced by serotype 1, but is always produced by strains of serotype 2; strains of other serotypes vary in indole production. All the serotypes have, at one time or another, been known by other designations, and these are shown in Table BXII.γ.276. Members are intestinal pathogens of humans and subhuman primates, causing bacillary dysentery. Humans are the primary reservoir. A long-term carrier state occurs in a small percentage of cases (Levine et al., 1973). Serotype 1 causes more severe disease than other serotypes and produces a potent protein exotoxin (Shiga toxin), which plays a role in the severity of the disease attributable to this serotype and in the development of hemolytic uremic syndrome in some individuals. Large epidemics in developing countries are commonly caused by serotype 1. Disease caused by other serotypes may be mild or severe.

The mol% G + C of the DNA is: 53 (chemical analysis; Laskin and Lechevalier (1981)).

Type strain: ATCC 13313, CIP 57.28, NCTC 4837.

GenBank accession number (16S rRNA): X96966.

Additional Remarks: Neotype strain ATCC 13313 was designated by Judicial Commission, 1963.

2. **Shigella boydii** Ewing 1949, 634, Epit. Spec. Cons. Opinion 11 of the Jud. Comm. 1954a, 149[AL]*
boy′di.i. M.L. gen. n. *boydii* of Boyd; named after Sir John Boyd, a British bacteriologist.

Catalase is produced. D-mannitol is fermented. Dulcitol is usually fermented by serotypes 2, 3, 4, 6, and 10, but this may be delayed. D-xylose fermentation is variable. Indole may or may not be produced. Gas-producing biotypes of *S. boydii* serotype 13 (Rowe et al., 1975) and serotype 14 (Carpenter, 1961) have been described. Members are intestinal pathogens of humans and subhuman primates, causing bacillary dysentery. Disease may be mild or severe. Humans are the primary reservoir. A long-term carrier state occurs in a small percentage of cases (Levine et al., 1973).

The mol% G + C of the DNA is: not determined.

Type strain: ATCC 8700, CIP 82.50, DSM 7532, NCTC 12985.

3. **Shigella flexneri** Castellani and Chalmers 1919, 937, Epit.

**Editorial Note:* This species is also known as subgroup A.

**Editorial Note:* This species is also known as subgroup C.

Spec. Cons. Opinion 11 of the Jud. Comm. 1954a, 149[AL]*
flex' ner.i. M.L. gen. n. *flexneri* of Flexner, named after Simon Flexner, an American bacteriologist.

Catalase is produced. D-mannitol is fermented, except by biotype Newcastle, serotype 6 and a D-mannitol negative, D-xylose positive biotype of serotype 4a (sometimes known as *"S. rabaulensis"*). Dulcitol is fermented by certain biotypes of serotype 6 (see Table BXII.γ.275), some of which produce gas from fermentable sugars. Indole is not produced by serotype 6; in other serotypes indole production is variable. Members are intestinal pathogens of humans and subhuman primates, causing bacillary dysentery. Humans are the primary reservoir. Disease may be mild or severe. A long-term carrier state occurs in a small percentage of cases (Levine et al., 1973). Infection in individuals with the HLA-B27 histocompatibility antigen can be complicated by Reiter chronic arthritis syndrome.

The mol% G + C of the DNA is: 49 (chemical analysis) (Laskin and Lechevalier, 1981) and 50.9 (nucleotide sequence analysis) (Jin et al., 2002) and (Wei et al., 2003).

Type strain: ATCC 29903, CIP 82.48, DSM 4782.

GenBank accession number (16S rRNA): X96963; complete genome: AE005673 and AE014073.

4. **Shigella sonnei** (Levine 1920) Weldin 1927, 182, Epit. Spec. Cons. Opinion 11 of the Jud. Comm. 1954a, 149[AL] (*Bacterium sonnei* Levine 1920, 31.)*
son' ne.i. M.L. gen. n. *sonnei* of Sonne, named after Carl Sonne, a Danish bacteriologist.

On deoxycholate citrate agar colonies are at first colorless, but after a few days show bright pink papillae consisting of lactose-fermenting cells. On MacConkey agar, phase I colonies are indistinguishable from colonies of other shigellas, but phase II colonies are larger, flatter, and more translucent, and have an irregular edge. On subculture, phase I colonies produce both phase I and phase II colonies, but phase II colonies give rise to phase II colonies only. D-mannitol is fermented rapidly, lactose and sucrose more slowly. Some strains may ferment D-xylose. Catalase is produced. Indole is not produced. Ornithine is decarboxylated; arginine may be decarboxylated. Members are intestinal pathogens of humans and subhuman primates, causing bacillary dysentery. Humans are the primary reservoir. A long-term carrier state occurs in a small percentage of cases (Levine et al., 1973). Illness is typically milder than that caused by members of the other *Shigella* subgroups.

The mol% G + C of the DNA is: 51 (CsCl buoyant density).

Type strain: ATCC 29930, CIP 82.49, DSM 5570, NCTC 12984.

Other Organisms

S. boydii 13 strains were first described in 1952 by Ewing and Hucks (1952) under the provisional designation "serotype 425". Six years later, serotype 425 was added to the *Shigella* scheme as *S. boydii* 13 (Ewing et al., 1958). The initial description of the serotype included 10 strains: eight from cases and two from carriers isolated from persons from Italy, Belgian Congo, Egypt, and the United States. Except for differences in their ability to grow on ammonium salts glucose agar, the strains were biochemically indistinguishable from each other and most closely resembled shigellae of subgroup C. In 1973, Brenner et al. (1973a) reported evidence from DNA–DNA reassociation studies of *Shigella* species challenging the placement of *S. boydii* 13 strains in the genus *Shigella*. These investigators found that the *S. boydii* 13 strains they examined were highly interrelated but averaged only about 65% relatedness to other shigellae or members of the genus *Escherichia*. In a subsequent study, Brenner et al. (1982c) published findings from additional *S. boydii* 13 strains that extended and confirmed the earlier observation that *S. boydii* 13 strains, both anaerogenic and aerogenic varieties, are separable from other shigellae and *E. coli* based on DNA relatedness. The DNA–DNA reassociation evidence clearly demonstrates that *S. boydii* 13 strains represent a new, as yet unnamed, species. More recent findings from MLEE (Ochman et al., 1983; Pupo et al., 1997), nucleotide sequence analysis of housekeeping genes (Pupo et al., 2000), ribotyping (Rolland et al., 1998), and esterase electrophoretic polymorphisms (Goullet and Picard, 1987) are consistent with a distant relationship between *S. boydii* 13 strains and the other shigellae. At present, *S. boydii* 13 strains are primarily isolated by clinical laboratories and routinely keyed out as belonging to the genus *Shigella*. Because practical and logical factors are important in considering changes to existing systems of taxonomy and nomenclature (Brenner et al., 1973a), the renaming or reclassification of these bacteria is dependent on the development of methods that are useful for their identification in clinical laboratories.

Genus XXXVI. **Sodalis** *Dale and Maudlin 1999, 273[VP]*

Colin Dale, Serap Aksoy, Susan C. Welburn, Ian Maudlin and Aharon Oren

so.da' lis. L. masc. n. *sodalis* a companion.

Cells rod-shaped. Nonmotile. Gram negative. Endospore formation not observed. **Microaerophilic.** Chemoorganotrophic. Axenic growth occurs in media with enzymatically digested proteins serving as carbon and nitrogen sources. **Certain carbohydrates are used with the production of acids.** The optimum temperature for growth is 25°C, with little or no growth occurring at temperatures >30°C. Catalase and oxidase negative. **Found as secondary intracellular symbiotic bacteria in insects.**

The mol% G + C of the DNA is: 53.5.

Type species: **Sodalis glossinidius** Dale and Maudlin 1999, 273.

Editorial Note: This species is also known as subgroup B; formerly known as *"S. paradysenteriae"* Flexner.

Editorial Note: This species is also known as subgroup D.

Further descriptive information

The genus *Sodalis* consists of maternally transmitted intracellular symbiotic bacteria inhabiting the hemolymph and other organs of insects. Most intracellular symbiotic bacteria of insects are fastidious, and have thus far proved refractory to conventional culture techniques. *Sodalis glossinidius*, a multitissue secondary intracellular symbiont of the tsetse fly (*Glossina morsitans*), was the first true intracellular symbiont from insects to be cultivated *in vitro*. Cultivation was first achieved through the use of a mosquito (*Aedes albopictus*) feeder cell culture system. Subsequently, the organism was isolated in pure culture on a semidefined solid medium under microaerobic conditions. Therefore, *Sodalis* is the first example of the successful cultivation of an insect secondary intracellular symbiont on an agar-based medium. Phylogenetic characterization of *Sodalis* strains from different tsetse species revealed no differences based on their 16S rDNA sequences (Chen et al., 1999b). Other insects related to the tsetse fly carry bacterial symbionts with 16S rDNA sequences very similar to the 16S rDNA of *Sodalis*, but these symbionts are still awaiting isolation.

Sodalis glossinidius, the only species of the genus described thus far, is microaerophilic and can be cultivated only on solid media under a reduced-oxygen atmosphere. An atmosphere of 5% oxygen and 95% carbon dioxide is optimal for growth. Alternatively, aerotolerance-enhancing supplements such as catalase or fresh horse blood as a source of catalase activity can be added to the plates to enable growth in air.

The biochemical capacities of *Sodalis glossinidius* are rather restricted. Among the few carbohydrates used for growth the most efficient are *N*-acetyl-D-glucosamine and raffinose, which are metabolized with massive acid production. Glucose, glycol chitosan, mannitol, and sorbitol are metabolized to a lesser extent.

Sodalis glossinidius has a chromosome of about 2 Mb and about 134 kb plasmid DNA (Akman et al., 2001). Its chromosomal DNA is subject to extensive adenine and cytosine methylation. Hybridization of *Sodalis* DNA to *Escherichia coli* macroarrays revealed the presence of about 1800 orthologs, indicating that *Sodalis* has retained many of the capabilities of free-living bacteria. Based on this analysis, it appears that *Sodalis* has retained many genes involved in transcription, translation, regulation, nucleic acid, and amino acid biosynthetic pathways. However, it is possible that *Sodalis* might have lost genes in carbon compound catabolism, central intermediary metabolism, and fatty acid and phospholipid metabolism, which could account for the organism's restricted biochemical capacities.

To enter into insect cells, *Sodalis* uses a type III secretion system invasion gene (*invC*), very similar to virulence determinants previously identified in the genera *Salmonella* and *Shigella* (Dale et al., 2001).

Enrichment and Isolation Procedures

Sodalis glossinidius has been isolated from the hemolymph of *Glossina morsitans morsitans* in coculture with the mosquito *Aedes albopictus* cell line C6/36 (Welburn et al., 1987). Pure culture isolation was achieved through the use of solid-phase culture on serum-free Mitsuhashi-Maramorosch basal medium (Igarashi, 1978) with 1% Bacto-agar (Difco) under a microaerobic atmosphere (O_2/CO_2; 5:95). For growth under an air atmosphere, aerotolerance-enhancing supplements such as catalase or fresh horse blood cells (as source of catalase activity) should be added.

Maintenance Procedures

Sodalis glossinidius can be maintained by coculture in *Aedes albopictus* C6/36 cells at 25°C in liquid Mitsuhashi-Maramorosch medium (Igarashi, 1978) supplemented with 20% (v/v) heat-inactivated fetal calf serum by passaging the cells every 10 d (Welburn et al., 1987). For long-time storage bacterial cells are frozen in Mitsuhashi-Maramorosch medium supplemented with 20% (v/v) heat-inactivated fetal calf serum and 15% (v/v) glycerol.

Taxonomic Comments

Sodalis was classified in the family *Enterobacteriaceae* based on phenotypic tests and its 16S rDNA sequence. As a microaerophilic insect symbiont, it differs sufficiently from the other described genera within the *Enterobacteriaceae* to warrant classification as a separate genus. Different species and subspecies of tsetse flies harbor intracellular symbionts having almost identical 16S rDNA sequences (Beard et al., 1993; Aksoy et al., 1997). In addition, other insects, including flour and rice weevils and certain psyllids also harbor intracellular symbionts with closely related 16S rDNA sequences (Thao et al., 2000a).

Sodalis harbors type III secretion system invasion genes that are phylogenetically related to those found previously in *Salmonella enterica* and *Shigella flexneri*.

List of species of the genus Sodalis

1. **Sodalis glossinidius** Dale and Maudlin 1999, 273.[VP]

glos.si.ni′ di.us. N.L. adj. *glossinidius* of the genus *Glossinia*.

The characteristics are as described for the genus, with the following additional information. The cells are 1.0–1.5 × 2.0–12.0 μm. When grown intracellularly in *Aedes albopictus* cell culture, the organisms appear as pleomorphic rods. Temperature range for growth: 18–28°C. Colonies on Mitsuhashi-Maramorosch agar (Igarashi, 1978) are shiny, off-white, and concave, with entire edges.

Negative for DNase, gelatinase, urease, nitrate reductase, indole production, hippurate hydrolysis, arginine dihydrolase, lysine decarboxylase, ornithine decarboxylase, phenylalanine decarboxylase, and starch hydrolysis. Produces α-galactosidase and β-*N*-acetylglucosaminidase. Does not produce α-fucosidase, β-galactosidase, α-glucosidase, β-glucosidase, β-glucuronidase, α-mannosidase, and β-xylosidase. Utilization of *N*-acetyl-D-glucosamine and raffinose accompanied by a high level of acid production. Utilizes glucose, glycol chitosan, mannitol, and sorbitol with accompanying weak acid production. No increase in growth is detected

when any of the following carbon sources are incorporated in the media: acetic acid, adonitol, δ-aminovaleric acid, L-arabinose, *n*-butanol, citric acid, dulcitol, ethanol, fructose, fumaric acid, galactose, glycerol, glycolic acid, histamine, *p*-hydroxybenzoic acid, α-ketoglutaric acid, lactose, D,L-malic acid, maltose, mannose, melibiose, methyl-α-D-glucopyranoside, *myo*-inositol, n-propanol, pyruvic acid, quinic acid, rhamnose, ribose, saccharic acid, salicin, sarcosine, sorbose, succinic acid, sucrose, starch, trehalose, or xylose.

Contains a number of large extrachromosomal DNA elements.

Found as secondary intracellular symbionts in the midgut, fat body, and hemolymph of the tsetse fly *Glossina morsitans morsitans*.

The mol% G + C of the DNA is: 53.5 (T_m).

Type strain: M1, NCIMB 13495.

GenBank accession number (16S rRNA): M99060.

Genus XXXVII. **Tatumella** *Hollis, Hickman and Fanning 1982, 267[VP] (Effective publication: Hollis, Hickman, Fanning, Farmer, Weaver and Brenner 1981, 86) (Group EF-9 Hollis, Hickman, Fanning, Brenner and Weaver 1980)*

J.J. FARMER III

Ta.tum.el' la. M.L. dim. neut. *-ella* ending; M.L. fem. n. *Tatumella* named to honor Harvey Tatum, an American bacteriologist who made many contributions to our understanding of the classification and identification of fermentative and nonfermentative bacteria of medical importance.

Small rod-shaped cells 0.6–0.8 × 0.9–3 µm, conforming to the general definition of the family *Enterobacteriaceae*. Contains the enterobacterial common antigen. Gram negative. **Nonmotile at 36°C; over half the strains are motile by means of polar, subpolar, or lateral flagella when grown at 25°C.** Facultatively anaerobic. Catalase positive (weak and slow). Oxidase negative. Nonpigmented. **Stock cultures often die within a few weeks on laboratory media. Biochemically more active at 25°C than at 36°C.** Ferment, rather than oxidize, D-glucose; without the formation of visible gas. Reduce nitrate to nitrite. **Very inactive biochemically; positive tests only for Voges–Proskauer (Coblentz method), phenylalanine deaminase, and fermentation of sucrose, trehalose, and D-mannose. Negative for most tests**: indole production, methyl red, Voges–Proskauer (O'Meara method), citrate utilization (Simmons), H_2S production (TSI), urea hydrolysis, lysine decarboxylase, arginine dihydrolase, ornithine decarboxylase, growth in the presence of cyanide (KCN test), malonate utilization, esculin hydrolysis, ONPG, gelatin hydrolysis (22°C), lipase (corn oil), DNase, gas production during fermentation, and the fermentation of lactose, D-mannitol, dulcitol, adonitol, *myo*-inositol, D-sorbitol, L-arabinose, raffinose, L-rhamnose, maltose, D-xylose, cellobiose, α-methyl-D-glucoside, erythritol, D-arabitol, glycerol, and mucate. Have very large zones of inhibition around antibiotics; susceptible to colistin, nalidixic acid, sulfadiazine, gentamicin, streptomycin, kanamycin, tetracycline, chloramphenicol, carbenicillin, ampicillin, and cephalothin (disk diffusion method on Mueller–Hinton agar). **Large zone of inhibition around a penicillin G (10 U) disk, in contrast to most other *Enterobacteriaceae*.**

Isolated from human clinical specimens, mainly from the **respiratory tract** where clinical significance is questionable. Also isolated from blood cultures suggesting clinical significance. Probably **a rare opportunistic pathogen or colonizer of humans**.

The mol% G + C of the DNA is: 53–54.

Type species: **Tatumella ptyseos** Hollis, Hickman and Fanning 1982, 267 (Effective publication: Hollis, Hickman, Fanning, Farmer, Weaver and Brenner 1981, 86.)

FURTHER DESCRIPTIVE INFORMATION

Literature Since *Tatumella* was described in 1981, there have been only a few reports in the literature. In addition to the genus and species names, "EF-9" should also be included as a search term in computerized literature searches, although it is rarely used today.

The *Tatumella* literature reports include reviews and taxonomic studies of new *Enterobacteriaceae* (Gilchrist, 1995; Aleksic and Bockemühl, 1999), and surveys or comparisons of the family *Enterobacteriaceae* for evolutionary relatedness based on 16S rRNA sequencing (Spröer et al., 1999), the enterobacterial common antigen (Ramia et al., 1982), catalase production (Chester and Moskowitz, 1987), metabolic pathways (Bouvet and Grimont, 1987a; Bouvet et al., 1989), polyamines (Hamana, 1996), and siderophores (Rabsch and Winkelmann, 1991).

Sources, strains, collections Strains of *Tatumella* have been isolated from a variety of human clinical specimens, but not from other sources. The original collection of Hollis et al. (1981) included isolates from body sites that are normally sterile such as blood (three isolates) and urine (one), but 38 were from throat, pharynx, tracheal aspirate, or sputum. One was from feces.

Clinical significance of human isolates The clinical significance and the ability of *T. ptyseos* to actually cause infections should be carefully evaluated in cases that yield this organism. Systematic study and good case reports are needed. Tan et al. (1989) reported a case of presumed sepsis in a neonate with jaundice who recovered uneventfully after treatment with antibiotics. This report and the three blood isolates described by Hollis et al. (1981) suggest that *T. ptyseos* should at least be considered as a rare opportunistic pathogen.

Isolation, identification, culture preservation, phenotypic characterization Strains of *Tatumella* are not difficult to grow, but may grow more slowly than typical *Enterobacteriaceae*. Stock cultures may die within a few weeks on agar or in semisolid stock culture media. This characteristic is very unusual, since most cultures of *Enterobacteriaceae* can be kept almost indefinitely in sealed tubes kept at room temperature. *Tatumella* cultures frozen in 5% rabbit blood and stored at −40°C to −60°C have remained viable after storage for up to 14 years. This latter method or storage in liquid nitrogen (or perhaps freeze-drying) should be suitable for long-term preservation. See the chapter on the family *Enterobacteriaceae* for general information on growth, plating media, working and frozen stock cultures, media and methods for

biochemical testing, identification, computer programs, and antibiotic susceptibility. On MacConkey agar at 24 h, all strains grew and produced colorless (lactose negative) colonies.

Biochemical reactions and differentiation from other *Enterobacteriaceae* Table BXII.γ.193 in the chapter on the family *Enterobacteriaceae* gives the results for *Tatumella* in 47 biochemical tests normally used for identification (Farmer, 1999). The most striking feature of *T. ptyseos* strains is their biochemical inactivity. They are also more active biochemically at 25°C than 36°C. The flagellation of *Tatumella* is also unusual. Strains are nonmotile at 36°C, but 66% are motile at 25°C. No flagella are produced on most cells, but those seen are polar, subpolar, or lateral rather than peritrichous. In contrast to most other *Enterobacteriaceae*, cultures of *T. ptyseos* have large zones of inhibition around 10 U penicillin G disks (range of 15–36 mm, mean of 24 mm, standard deviation of 4.6 mm). There are no genus- or species-specific tests or sequences for the identification of *Tatumella*. The best approach is to do a complete set of phenotypic tests (growth on plating media, biochemical tests, antibiogram, etc.) and compare the results with all the other named organisms in the family *Enterobacteriaceae*. This approach is described in more detail in the section on *Enterobacteriaceae*. The biochemical results of a test strain can be compared to all the organisms listed in Table BXII.γ.193 in the chapter on the family *Enterobacteriaceae*. Several computer programs greatly facilitate analyzing the results.

Taxonomic Comments

History The name *Tatumella* was coined by Hollis et al. (1981) for a group of organisms that had previously been known as "Group EF-9", a name coined and used by the Special Bacteriology Section at the Centers for Disease Control (Hollis et al., 1980). Group EF-9 had been known for many years, but its taxonomic position had not been studied.

Circumscription of *T. ptyseos* (Hollis et al., 1981) Twenty-seven "suspect" strains of Group EF-9 were studied by DNA–DNA hybridization, biochemical reactions, and antibiotic susceptibility. Twenty of the strains were very highly related to the type strain (89% or greater with ΔT_m values of 0–0.5) by DNA–DNA hybridization (60°C, hydroxyapatite method with ^{32}P). A group of six strains was less related (80–90% with ΔT_m values of 5.4–7.8), but was included in the species *T. ptyseos*. These strains may eventually be classified as one or more distinct biogroups. One strain (H34) was considerably less related (66% related at 60°C, which dropped to 44% at 75°C), and was not included in *T. ptyseos*. This probably represents a second species of *Tatumella*. By DNA hybridization, other taxa in the family *Enterobacteriaceae* were related by 7–38%, including 25–30% relatedness of *Escherichia*, the type genus of the family. Based on the DNA–DNA hybridization and phenotypic data, Group EF-9 was proposed as a new genus, *Tatumella*, with *T. ptyseos* as the only species (Hollis et al., 1981).

Phylogeny based on 16S rRNA sequencing A 16S rRNA tree that includes *T. ptyseos* can be found in Fig. BXII.γ.198 in the chapter on the genus *Budvicia* in this *Manual*. The 16S rRNA sequencing data agree with DNA–DNA hybridization and phenotypic data that *Tatumella* is a distinct genus of *Enterobacteriaceae*. This tree generally agrees with the tree published by Spröer et al. (1999), in that *Tatumella* is on a distinct branch. However, the two trees differ in the placement of the closest neighbors and other organisms (see also Fig.BXII.γ.189 in the chapter on the family *Enterobacteriaceae*).

Nomenclatural problem: the irregular author citation in the names *Tatumella* Hollis, Hickman and Fanning 1982, 267 ^{VP} and *Tatumella ptyseos* Hollis, Hickman and Fanning 1982, 267 ^{VP} The author citation for the names *Tatumella* and *Tatumella ptyseos* has traditionally been written as "Hollis, Hickman and Fanning 1982, 267 ^{VP}" rather than the expected citation of "Hollis, Hickman, Fanning, Farmer, Weaver and Brenner 1982, 267^{VP}". The original paper (Hollis et al., 1981) had six authors rather than three, but on page 86 the authors stated: "We propose the following citations of the genus and species, which recognizes the greater contribution of three of the authors: *Tatumella* Hollis, Hickman and Fanning; *Tatumella ptyseos* Hollis, Hickman and Fanning."

This irregular author citation continued through correspondence with the editor of the *International Journal of Systematic Bacteriology* that requested validation of the genus and species name. In Validation List 8, the request for a "three-author citation" was granted and was without comment since only three authors, "Hollis, Hickman and Fanning", were listed under the column heading "Author(s)" for both names. This unusual citation appears to conflict with the rules of the Bacteriological Code (International Code of Nomenclature of Bacteria) for citing authors of new taxa. Although this is a small point, it is one that can lead to instability in nomenclature. The problem could be addressed by amending the Bacteriological Code, or through an Opinion of the Judicial Commission.

Hollis, D.G., F.W. Hickman, G.R. Fanning, J.J. Farmer, III, R.E. Weaver and D.J. Brenner. 1981. *Tatumella ptyseos* gen. nov., sp. nov., a member of the family *Enterobacteriaceae* found in clinical specimens. J. Clin. Microbiol. *14*: 79–88.

List of species of the genus Tatumella

1. **Tatumella ptyseos** Hollis, Hickman and Fanning 1982, 267^{VP} (Effective publication: Hollis, Hickman, Fanning, Farmer, Weaver and Brenner 1981, 86.)
pty' se.os. Gr. n. *ptyseos* a spitting (or less literally from sputum, the most common source of clinical isolates).

The characteristics are as given for the genus and the results for 47 biochemical tests are given in Table BXII.γ.193 of the chapter on the family *Enterobacteriaceae*. Isolated from human clinical specimens, primarily from the respiratory tract; should probably be considered a rare opportunistic pathogen.

The mol% G + C of the DNA is: 53–54 (Bd).

Type strain: H36, ATCC 33301, CDC D6168, CDC 9591-78, DSM 5000.

GenBank accession number (16S rRNA): AJ233437.

Additional Remarks: Hollis et al. (1981) include 25 other strains in the species; however, six of these were less related to the type strain that the others (see previous discussion). One additional strain (very highly related to the type strain) was also deposited in the American Type Culture Collection (ATCC 33302 [H3 9558-78 = A7744]), from human sputum, Connecticut, USA.

Genus XXXVIII. **Trabulsiella** *McWhorter, Haddock, Nocon, Steigerwalt, Brenner, Aleksic, Bockemühl and Farmer 1992, 327^VP (Effective publication: McWhorter, Haddock, Nocon, Steigerwalt, Brenner, Aleksic, Bockemühl and Farmer 1991, 1482) (Enteric Group 90 Murlin, Brenner, Steigerwalt and Farmer 1988)*

John A. Lindquist and J.J. Farmer III

Tra.bul.si.el'la. M.L. dim. ending *-ella;* M.L. fem. n. *Trabulsiella* named to honor L.R. Trabulsi, a Brazilian bacteriologist who did many important studies on the enteric pathogens of the family *Enterobacteriaceae*.

Rod-shaped cells, conforming to the general definition of the family *Enterobacteriaceae.* Gram negative. Motile. Facultatively anaerobic. Catalase positive. Oxidase negative. Ferment, rather than oxidize, D-glucose and other carbohydrates and produce visible gas during fermentation. Reduce nitrate to nitrite. **Positive for methyl red, citrate utilization (Simmons), H_2S production (TSI), lysine decarboxylase, ornithine decarboxylase, motility at 36°C, growth in the presence of cyanide (KCN test), esculin hydrolysis, ONPG, tyrosine hydrolysis, and the fermentation of D-mannitol, salicin, D-sorbitol, L-arabinose, L-rhamnose, maltose, D-xylose, trehalose, cellobiose, esculin, mucate, D-mannose, and D-galactose. Arginine dihydrolase is positive, but delayed.** Negative for Voges–Proskauer, urea hydrolysis, phenylalanine deaminase, malonate utilization, gelatin hydrolysis (22°C), lipase (corn oil), DNase, and the fermentation of sucrose, dulcitol, adonitol, *myo*-inositol, raffinose, α-methyl-D-glucoside, erythritol, melibiose, and D-arabitol. **Biochemically similar to, and can be confused with, *Salmonella* in routine screening tests. Do not completely type in *Salmonella* O or H antisera, and are negative in the *Salmonella*-specific test: lysis by bacteriophage O1, MUCAP (4-methylumbelliferyl caprylate), and a commercial gene probe (Gene-Trak Systems).** Susceptible to colistin, nalidixic acid, gentamicin, streptomycin, kanamycin, tetracycline, chloramphenicol, and carbenicillin; **resistant to penicillin, ampicillin, and cephalothin**; variable resistance to sulfadiazine and carbenicillin (disk diffusion method on Mueller–Hinton agar).

Ecological niches are not known, but have been isolated from environmental samples and human feces. However, there is **no evidence that *Trabulsiella* causes diarrhea or intestinal infections**. Apparently a **very rarely isolated genus of *Enterobacteriaceae*.**

The mol% G + C of the DNA is: not determined.

Type species: **Trabulsiella guamensis** McWhorter, Haddock, Nocon, Steigerwalt, Brenner, Aleksic, Bockemühl and Farmer 1992, 327 (Effective publication: McWhorter, Haddock, Nocon, Steigerwalt, Brenner, Aleksic, Bockemühl and Farmer 1991, 1483.)

Further descriptive information

Literature Since *Trabulsiella* was described in 1991, there have been only a few reports in the literature. In addition to the genus and species names, "Enteric Group 90" should also be included as a search term in computerized literature searches, although it is rarely used today.

Sources Six strains of *Trabulsiella* were isolated from vacuum cleaner dust on the island of Guam, three were from human stool specimens (one from New York, USA, and two from Germany), one was from wheat flour from Oregon, USA, and two were from environmental material (not further specified) in Malaysia. Many of these isolates were originally isolated and studied as "suspect *Salmonella* cultures".

Isolation, identification, culture preservation, phenotypic characterization Strains of *Trabulsiella* are not difficult to grow, and are typical *Enterobacteriaceae* in most respects. See the chapter on the family *Enterobacteriaceae* for general information on growth, plating media, working and frozen stock cultures, media and methods for biochemical testing, identification, computer programs, and antibiotic susceptibility. Strains of *Trabulsiella* will often appear as typical *Salmonella* strains on some enteric plating and screening media; however, they do not type completely in *Salmonella* O and H antisera.

Biochemical reactions and differentiation from other *Enterobacteriaceae* Table BXII.γ.193 in the section on the family *Enterobacteriaceae* gives the results for *Trabulsiella* in 47 biochemical tests normally used for identification (Farmer, 1999). There are no genus- or species-specific tests or sequences for the identification of *Trabulsiella.* The best approach is to do a complete set of phenotypic tests (growth on plating media, biochemical tests, antibiogram, etc.) and compare the results with all the other named organisms in the family *Enterobacteriaceae.* This approach is described in more detail in the chapter on the family *Enterobacteriaceae.* The biochemical results of a test strain can be compared to all the organisms listed in Table BXII.γ.193 of that chapter. Several computer programs greatly facilitate analyzing the results. *Trabulsiella* strains are phenotypically most like *Salmonella* subgroups 4 and 5, which are rarely isolated from human clinical specimens.

Taxonomic Comments

In 1985 the vernacular name Enteric Group 90 was coined for a group of strains that had been studied at the *Salmonella* Laboratory at the Centers for Disease Control and Prevention. From 1985 to 1988 eight strains were characterized that were phenotypically distinct from all of the described organisms in the family *Enterobacteriaceae.* They had been submitted as "biochemically *Salmonella*, but will not serotype". Since the strains were biochemically very close to *Salmonella*, particularly to *Salmonella* DNA hybridization groups 4 and 5, they were originally suspected as being a new DNA hybridization group in the genus *Salmonella.* However, by DNA–DNA hybridization the strains were very highly related to each other, but were more distantly related to other organisms in the family *Enterobacteriaceae.* Strain ATCC 49490 (CDC 370-85) that eventually became the type strain of *Trabulsiella guamensis* was 41% related by DNA–DNA hybridization to *Salmonella* serotype Typhimurium and to a strain of *Salmonella* DNA hybridization group 3b. Less relatedness was found to *Kluyvera ascorbata* (39%), *Shigella flexneri* (38%), *Klebsiella terrigena* (38%), and strain 6003-71 of the *Enterobacter agglomerans* complex (38%). Other *Enterobacteriaceae* were 6–37% related. Because strains of Enteric Group 90 were distinct by both DNA–DNA hybridization and phenotype, a new genus *Trabulsiella* with a single species *Trabulsiella guamensis* was proposed (McWhorter et al., 1991). *Trabulsiella* and *Trabulsiella guamensis* gained standing in nomenclature in 1992 when they appeared on Validation List 41 (McWhorter et al., 1992).

Further Reading

McWhorter, A.C., R.L. Haddock, F.A. Nocon, A.G. Steigerwalt, D.J. Brenner, S. Aleksic, J. Bockemuehl and J.J. Farmer, III. 1991. *Trabulsiella guamensis*, a new genus new species of the family *Enterobacteriaceae* that resembles *Salmonella* subgroups 4 and 5. J. Clin. Microbiol. *29*: 1480–1485.

List of species of the genus Trabulsiella

1. **Trabulsiella guamensis** McWhorter, Haddock, Nocon, Steigerwalt, Brenner, Aleksic, Bockemühl and Farmer 1992, 327^{VP} (Effective publication: McWhorter, Haddock, Nocon, Steigerwalt, Brenner, Aleksic, Bockemühl and Farmer 1991, 1483.)
guam.en′sis. M.L. adj. *guamensis* pertaining to Guam, the largest island of the Micronesian group of the Pacific Ocean, where the first strains were isolated.

The characteristics are as given for the genus. Isolated from environmental samples, food, and human feces. However, there is no evidence that *Trabulsiella guamensis* can cause diarrhea or intestinal infections. Apparently it is a very rarely isolated species of *Enterobacteriaceae*, whose importance in microbiology may be more as a nuisance, because of its biochemical similarity to *Salmonella* and possible misidentification as *Salmonella*. The type strain was isolated from vacuum cleaner contents on the island of Guam obtained during a survey to isolate *Salmonella* from environmental reservoirs, and to look at the role of reptile feces as a source of *Salmonella* infections. Vacuum cleaner contents were a convenient sample of "indoor dirt".

In the addendum section of their paper, McWhorter et al. (1991) described two different biochemical patterns given by *T. guamensis* strains, but they did not name them as biogroups. The eight strains from the United States and Guam were negative for indole production, gelatin hydrolysis (film method, 36°C), and esculin hydrolysis (within 2 d), but the four strains from Germany and Malaysia were positive. Strain 2421-87 (feces, Germany) was the only one of the original eight strains studied that had this latter pattern, but it was 98% related to the type strain by DNA–DNA hybridization at 60°C and the value did not drop when the temperature was raised to 75°C. Thus, the available data indicate that the two groups of strains should be considered as biogroups of *T. guamensis*.

The mol% G + C of the DNA is: not determined.

Type strain: ATCC 49490, CDC 0370-85.

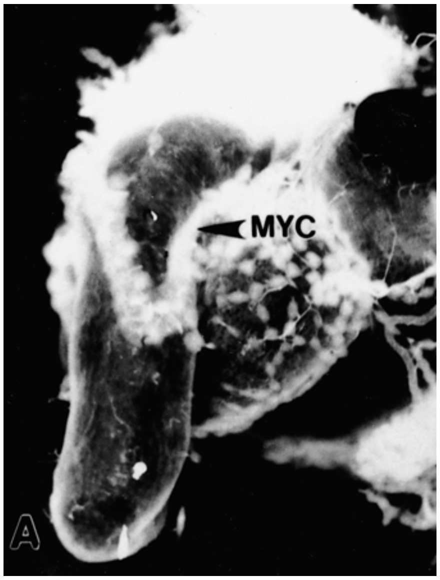
Additional Remarks: The American Type Culture Collection includes four other strains of *Trabulsiella guamensis* including strain ATCC 49493 (CDC 2421-87, from human feces, Germany) that is from the indole-positive biogroup described above.

The biochemical and geographic differences of the two groups of strains may reflect evolutionary divergence that should be investigated with methods other than DNA–DNA hybridization that measure relatedness. J.J. Farmer (unpublished data) recently found a group of three strains in the collection of the Enteric Reference Laboratory, CDC that were very similar to *Trabulsiella*, but were H_2S negative. These could represent a second species of *Trabulsiella*.

Genus XXXIX. **Wigglesworthia** *Aksoy 1995b, 849*^{VP}

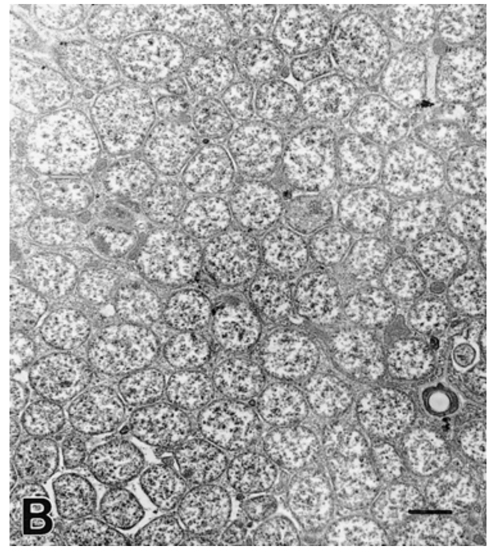
Serap Aksoy

Wigg.les.worth′i.a. M.L. fem. n. *Wigglesworthia* named after the parasitologist W.B. Wigglesworth.



Obligate intracellular, bacteriome-tissue associated, primary endosymbionts of tsetse flies. In the adult fly, the bacteria lie free in the cytoplasm of differentiated epithelial cells, bacteriocytes, which form the U-shaped bacteriome organ (previously referred to as mycetome) in the anterior midgut (Figs. BXII.γ.210A, B). The endosymbionts are rod shaped (2–4 × 8–10 μm) with a typical Gram-negative cell wall and inner membrane structure, lack flagella (Fig. BXII.γ.210C). The cells appear to divide by binary fission. The bacteria are obligate intracellular organisms, as their experimental elimination from tsetse by procaryotic-specific antibiotic treatment, by lysozyme, or with symbiont-specific antibodies provided in the blood meal results in retarded growth of the insect and a decrease in egg production, causing loss of the ability of these aposymbiotic hosts to reproduce (Hill et al., 1973; Nogge, 1976, 1978, 1980). In addition to *Wigglesworthia*, tsetse harbors a secondary (S)-symbiont in midgut tissue. The specific function(s) of *Wigglesworthia* and S-symbionts are not known; however, since the ability to reproduce can be partially restored when the aposymbiotic tsetse receive a blood meal that is supplemented with B-complex vitamins (thiamine, pantothenic acid, pyridoxine, folic acid, and biotin), it is suggested that the gut-tissue associated endosymbionts may play a role in metabolism that involves these compounds (Nogge, 1981). The recently sequenced genome of *Wigglesworthia* shows the presence of various biosynthetic pathways for vitamin metabolites (Akman et al., 2002). The 16S rDNA-based phylogeny of *Wigglesworthia* characterized from eight different tsetse species displays concordance with their insect host species, indicating an ancient association for this bacterium with an ancestral tsetse that has subsequently radiated along with the host insect species (Chen et al., 1999b). The bacterium is not present in the ovaries, but may be transmitted to the intrauterine larvae of tsetse via its milk-gland secretions.

Type species: **Wigglesworthia glossinidia** Aksoy 1995b, 849.



Further descriptive information

Various insects that rely on a single food source (blood or phloem) have established symbiotic associations with microorganisms in order to supplement their limited diets. Stuhlman found bacteria in the intestines of tsetse (Stuhlmann, 1907) and Roubaud described a mycetome (bacteriome)-like organ in midgut (Rouboud, 1919) that was confirmed by Wigglesworth and Buxton (Wigglesworth, 1929; Buxton, 1955). In ultrastructural studies, Reinhardt et al. (1972) described the large bacteroid found in tsetse mycetomes, and Pinnock and Hess (1974) distinguished these organisms from the smaller S-symbionts found in midgut tissue.

The well-defined bacteriome structure in tsetse guts can be

Aksoy et al., Insect Molecular Biology, *4:* 15–22, 1995, ©Blackwell Science Ltd., Oxford.) *B*, Electron micrograph of *Wigglesworthia* showing the packed endosymbionts in the bacteriocytes of *G. morsitans.* The endosymbionts are surrounded by a double-membrane (× 5000; bar = 4 μm). *C*, Dissected bacteriomes: (*a*) from a female maintained on a regular blood meal, and (*b*) from female that has received an antibiotic containing blood meal for one week. The bacteriome structure in the presence of antibiotics has disintegrated. (Reproduced with permission from S. Aksoy et al., Insect Molecular Biology, *4:* 15–22, 1995, ©Blackwell Science Ltd., Oxford.)

dissected and transiently maintained in tissue culture (Wink, 1979). Gene expression studies *in vivo* and *in vitro* have shown one of the major gene products of *Wigglesworthia* to be a molecular-chaperonin, the *groEL* homolog of *Escherichia coli* (Aksoy, 1995a). The overexpression of stress-related proteins has also been reported for the bacteriome endosymbionts of aphids (Kakeda and Ishikawa, 1991) and may be due to the intracellular nature of these microorganisms. PCR-based experiments show that *Wigglesworthia* is not present in ovary tissue (O'Neill et al., 1993), thus ruling out a transovarial transmission route; however, previous microscopy studies have reported the presence of microorganisms with similar morphology in milk-gland tissue of tsetse (Ma and Denlinger, 1974). Thus, milk-gland secretions may provide a route for the maternal transmission of *Wigglesworthia* to the intrauterine larvae of tsetse.

The S-symbionts of tsetse harbored in midgut-tissue and *Wolbachia* harbored in ovary tissue are morphologically different from *Wigglesworthia.* They are short rods (1–2 μm in length), and inside host cells they are surrounded by host membranes. There is a clear lytic zone around the cells reminiscent of true *Rickettsiaceae* to which the genus *Wolbachia* is related. Since phylogenetic analysis of tsetse S-symbionts has shown them to be enteric microorganisms, it is not clear what this lytic zone signifies (Reinhardt et al., 1972). The organization and copy number of the 16S rDNA gene in *Wigglesworthia* is different from *Buchnera* (the phylogenetically closely related P-endosymbionts of aphids), tsetse S-symbionts, and *E. coli.* The free-living bacterium *E. coli* and tsetse S-symbionts have multiple copies of rDNA operons encoding the 16S and 23S gene products. *Wigglesworthia* was shown to have a single operon encoding its 16S rDNA by Southern blot analysis (Aksoy, 1995a). The genome sequence analysis now indicates that there are two copies of the rDNA operon in *Wigglesworthia*, unlike the single operon found in *Buchnera* (Akman et al., 2002). In *Buchnera*, the 16S and 23S rDNA genes are not genetically linked, while in *Wigglesworthia* they are found to be transcriptionally linked (Aksoy, 1995a; Akman et al., 2002).

Taxonomic Comments

While it has not been possible to maintain the bacteriome-tissue symbionts *in vitro*, recent PCR-based amplification techniques and the use of nucleic acid sequences in phylogenetic recon-

structions have provided additional insight into the relationships among these intracellular bacteria. Their characterization from different species of aphids, whiteflies, carpenter ants, and tsetses have shown that they each form unique lineages within the *Gammaproteobacteria*, while the organisms from mealybugs are in the *Betaproteobacteria* and those associated with cockroaches are members of flavibacteria. Their phylogeny in each case has been found to parallel the phylogeny of their host insect species, indicating the ancient and obligatory nature of these symbiotic relationships (Baumann et al., 1998). The phylogeny of *Wigglesworthia* was analyzed from different flies representing the four species groups of genus *Glossina* (*morsitans*, *palpalis*, *machadomyia*, and *fusca*). For this analysis, the 16S rDNA sequence that is present as a single-copy gene was used (Aksoy et al., 1995; Chen et al., 1999b). The phylogenetic relationships of the tsetse host species were also analyzed by using an insect gene, the internal transcribed spacer-2 region of rDNA (ITS-2). These sequences were then used to generate phylogenetic alignments by maximum parsimony and two representative trees are shown in Fig. BXII.γ.211: for *Wigglesworthia* (Fig. BXII.γ.211b) and for the tsetse host species (Fig. BXII.γ.211a). The alignment of *Wigglesworthia* included the tsetse midgut S-symbiont clade and the S-symbionts of the weevil, *Sitophylus zeamais*; *Escherichia coli* was chosen as the out group. All trees generated could distinguish the tsetse symbionts, *Wigglesworthia*, and midgut S-symbionts, as distinct lineages within the *Gammaproteobacteria*. While within the S-symbiont clade no differences were observed in their 16S rDNA sequence, *Wigglesworthia* analyzed from the fusca group (*G. brevipalpis*) was found

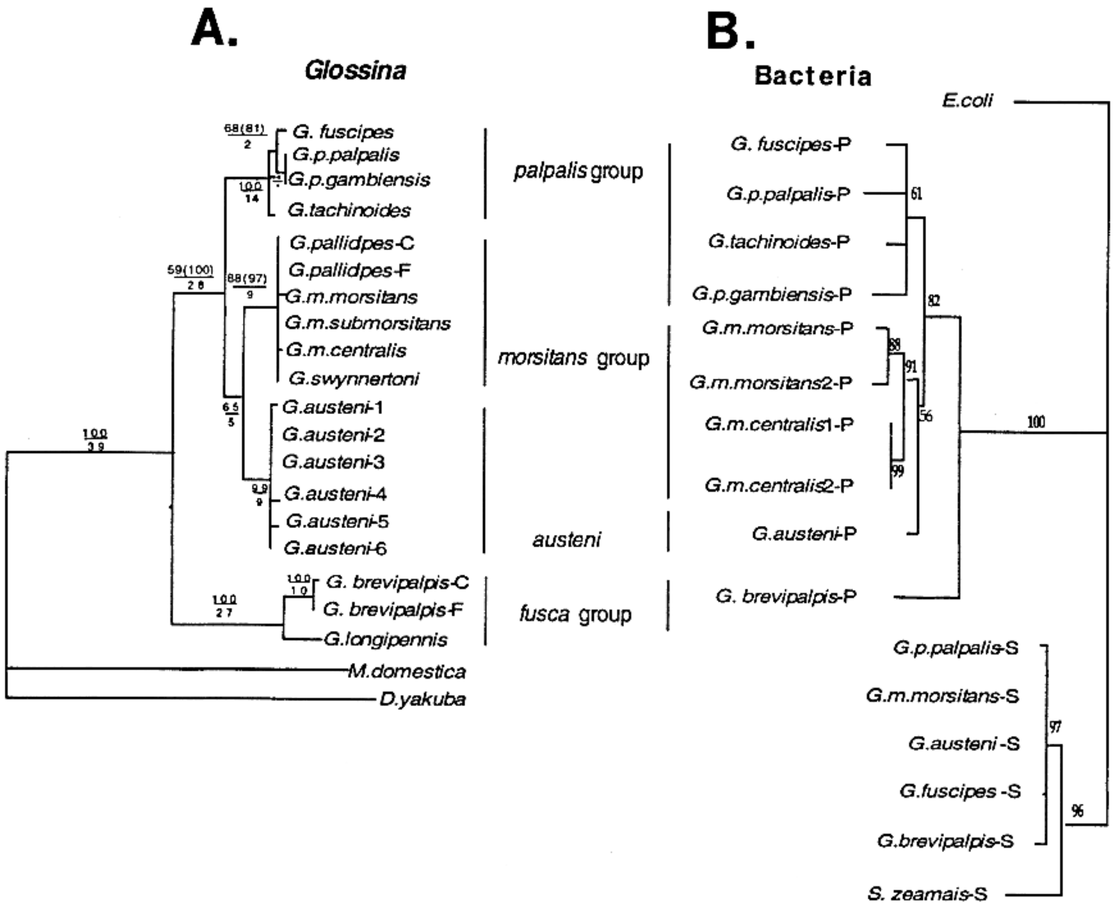

FIGURE BXII.γ.211. The phylogenetic placement of *Glossina* species and their symbionts. (Reproduced with permission from X. Chen et al., Journal of Molecular Evolution, *48:* 49–58, 1999, ©Springer-Verlag.) *A*, The phylogenetic tree constructed by maximum parsimony using the ITS-2 sequence. Tree length = 292, CI = 0.897. The bootstrap confidence values (300 replications) are presented at the nodes; the values in parentheses are bootstrap values where gaps have been included as weighted characters; numbers below denote branch length values. *D. yakuba* and *M. domestica* sequences are used as out groups. The grouping of the *palpalis*, *morsitans*, *austeni*, and *fusca* species are indicated. The origination of the *G. austeni* flies are as follows: *1*, colony maintained in Seibersdorf tsetse laboratories originating from Tanzania; *2*, field collected from Zanzibar; *3*, field collected from Shimba Hills (Kenya); *4*, colony established from Shimba Hills (Kenya); *5* and *6*, field collected from Hell's Gate Park in South Africa. *C* denotes flies analyzed from colonies. *F* denotes field isolates. *G. pallidipes*-C is from the colony at International Livestock Research Institute (ILRI) originating from Shimba Hills area of Kenya. *G. pallidipes*-F was a field collected fly from Nguruman region of Kenya. *G. brevipalpis*-C is from the colony at ILRI established from Kenya. *G. brevipalpis*-F is a field sample from South Africa. *B*, Phylogenetic analysis of *Wigglesworthia* and midgut S-symbionts based on their 16S rDNA sequence analysis. P denotes primary symbiont *Wigglesworthia*, and S denotes the secondary symbionts analyzed from the corresponding species of *Glossina*. *E. coli* was used as the out group. The analysis included 893 sites, of which 205 were variable and 121 were informative. One representative tree is shown (tree length 216, CI = 0.843, bootstrap values for 500 replications are shown at the nodes). *G. m. centralis*-1 was obtained from the colony maintained at ILRI in Kenya, while *G. m. centralis*-2 is from the colony maintained at Alberta and has originated from Zambia. The GenBank accession numbers for the 16S rDNA loci of *Wigglesworthia* from *G. p. gambiensis*, *G. m. morsitans*-2, *G. m. centralis*-1, *G. m. centralis*-2, *G. austeni*, and *G. fuscipes* are AF022875–AF022880, respectively.

to occupy the deepest branch. The *Wigglesworthia* sequences analyzed from the *morsitans* and *palpalis* group species formed sister taxa. The placement of *Wigglesworthia* from *G. austeni* (*machadomyia*), however, was less certain, since equally robust trees could be generated that differed only in the placement of *G. austeni* with respect to the other two subgenera. The low bootstrap-analysis confidence value (56) at the node where *G. austeni* symbiont forms a sister group with the *morsitans* species demonstrates this uncertainty. The ITS-2 sequence-based alignment (Fig. BXII.γ.211a) displayed similar phylogenetic relationships among the tsetse host species; the fusca flies were found to be the most divergent, while the *palpalis*, *morsitans*, and *machadomyia* subgenera were of more recent origin, and again the evolutionary relatedness of *machadomyia* with respect to the *palpalis* and *morsitans* subgenera could not be resolved with high confidence. The comparative analysis of the two phylogenies indicates their strong similarity, arguing for concordance of *Wigglesworthia* with their host tsetse species.

List of species of the genus Wigglesworthia

1. **Wigglesworthia glossinidia** Aksoy 1995b, 849[VP]
glos.si.nid′i.a. M.L. fem. adj. *glossinidia* referring to *Glossina*, the genus of tsetse flies.

The characteristics are as described for the genus and as depicted in Fig. BXII.γ.210.

The mol% G + C of the DNA is: not known.

Type strain: endosymbiont of Glossina morsitans morsitans.

GenBank accession number (16S rRNA): L37339.

Genus XL. **Xenorhabdus** *Thomas and Poinar 1979, 354[AL] emend. Thomas and Poinar 1983, 878*

RAYMOND J. AKHURST AND NOËL E. BOEMARE

Xe.no.rhab′dus. Gr. n. *xenos* unwanted guest (less literally, pathogen); Gr. fem. n. *Rhabdus* rod; M.L. masc. n. *Xenorhabdus* pathogenic rod-shaped bacterium.

Asporogenous, rod-shaped cells 0.3–2 × 2–10 μm and occasionally with filaments 15–50 μm in length. Spheroplasts, averaging 2.6 μm in diameter, appear in the last third of exponential growth. **Proteinaceous crystalline inclusions** develop in a large proportion of cells in stationary phase cultures. Gram negative. Motile by means of peritrichous flagella. Swarming may occur on 0.6–1.2% agar. Facultatively anaerobic, with both respiratory and fermentative types of metabolism. **Optimum temperature usually ~28°C or less**; a few strains grow at 40°C. Acid (no gas) production from glucose; ferment some other carbohydrates but poorly. **No catalase activity; nitrate is not reduced to nitrite.** Negative for most tests used to differentiate *Enterobacteriaceae*. Lipase detected with Tween 20 and egg yolk agar; most strains lipolytic on Tween 40, 60, 80, and/or 85. Positive for deoxyribonuclease and protease. **Phase shift occurs to varying degrees in stationary phase cultures**, giving rise to phase II, which lacks dye adsorption, antibiotic production, protein inclusions, and some other characteristics of the phase I isolated from the natural environment. **Only known from the intestinal lumen of entomopathogenic nematodes of the family** *Steinernematidae* and insects infected by these nematodes.

The mol% G + C of the DNA is: 43–50 (Bd).

Type species: **Xenorhabdus nematophila** (Poinar and Thomas 1965) Thomas and Poinar 1979, 355 (*Achromobacter nematophilus* Poinar and Thomas 1965, 249.)

FURTHER DESCRIPTIVE INFORMATION

Analyses of 16S rDNA sequences show that *Xenorhabdus* is most closely related to *Photorhabdus*, a genus composed largely of bacteria symbiotically associated with entomopathogenic nematodes of the family *Heterorhabditidae*. The next nearest phylogenetic neighbors are *Proteus vulgaris* and *Arsenophonus nasoniae* (Suzuki et al., 1996; Brunel et al., 1997; Liu et al. 1997a; Szállás et al., 1997).

Xenorhabdus species are insect pathogenic bacteria that occur naturally in the intestinal vesicle of nonfeeding infective stage entomopathogenic nematodes of the family *Steinernematidae* (Bovien, 1937; Poinar and Leutenegger, 1968; Bird and Akhurst, 1983). After invading an insect host, the nematode commences development, releasing *Xenorhabdus* into the nutrient-rich hemolymph. The bacteria proliferate, killing the insect host and producing suitable nutrient conditions for growth and reproduction of the nematodes as well as an array of antibiotics and bacteriocins to minimize competition. As the nutrient source becomes depleted, the immature nematodes develop into the infective stage that will transport *Xenorhabdus* to a new nutrient source. The association between each *Xenorhabdus* species and nematode is specific, with each nematode only naturally associated with a single *Xenorhabdus* species. However, *X. bovienii*, *X. poinarii*, and *X. beddingii* are each associated with more than one *Steinernema* species (Akhurst, 1983a, 1986b; Fischer-Le Saux et al., 1998).

A highly significant feature of bacteria of the genus *Xenorhabdus* is a phase variation that occurs in stationary phase (Akhurst, 1980). Only phase I *Xenorhabdus* have been detected in nature, but under *in vitro* conditions a variable proportion undergoes a profound change affecting colony and cell morphologies, motility, endo- and exo-enzymes, including respiratory enzymes, and secondary metabolites (Akhurst, 1980; Boemare and Akhurst, 1988; Smigielski et al., 1994; Givaudan et al. 1995; Fodor et al. 1997; Table BXII.γ.277). The timing and extent of phase change is largely unpredictable, but the rate of change from phase I to phase II is generally greater than the reverse. Phase I *Xenorhabdus* provide and protect essential nutrients for the nematodes by killing and metabolizing the insect host and producing a range of antimicrobial agents. Although phase II variants may also kill the insect host, they are less effective in providing growth conditions for the nematodes (Akhurst, 1980, 1982a), and have never been found associated with naturally occurring nematodes; the role of phase II is uncertain.

Xenorhabdus cells are rod-shaped cells that are highly variable in size, ranging from 0.3 × 2 μm to 2 × 10 μm with occasional

filaments 15–50 μm in length. Varying proportions of the cells occur as spheroplasts (diameter ~2.6 μm) in stationary phase cultures. Proteinaceous inclusion bodies, commonly two morphs, are evident in many of the rod-shaped phase I cells in stationary phase (Fig. BXII.γ.212). The glycocalyx surrounding *Xenorhabdus* cells is irregular in thickness, with a mean depth of 142 nm in phase I *X. nematophila** and 49 nm in phase II (Brehélin et al.,

Editorial Note: Xenorhabdus nematophila was originally named *Xenorhabdus nematophilus*; the name was corrected by Euzéby and Boemare (2000).

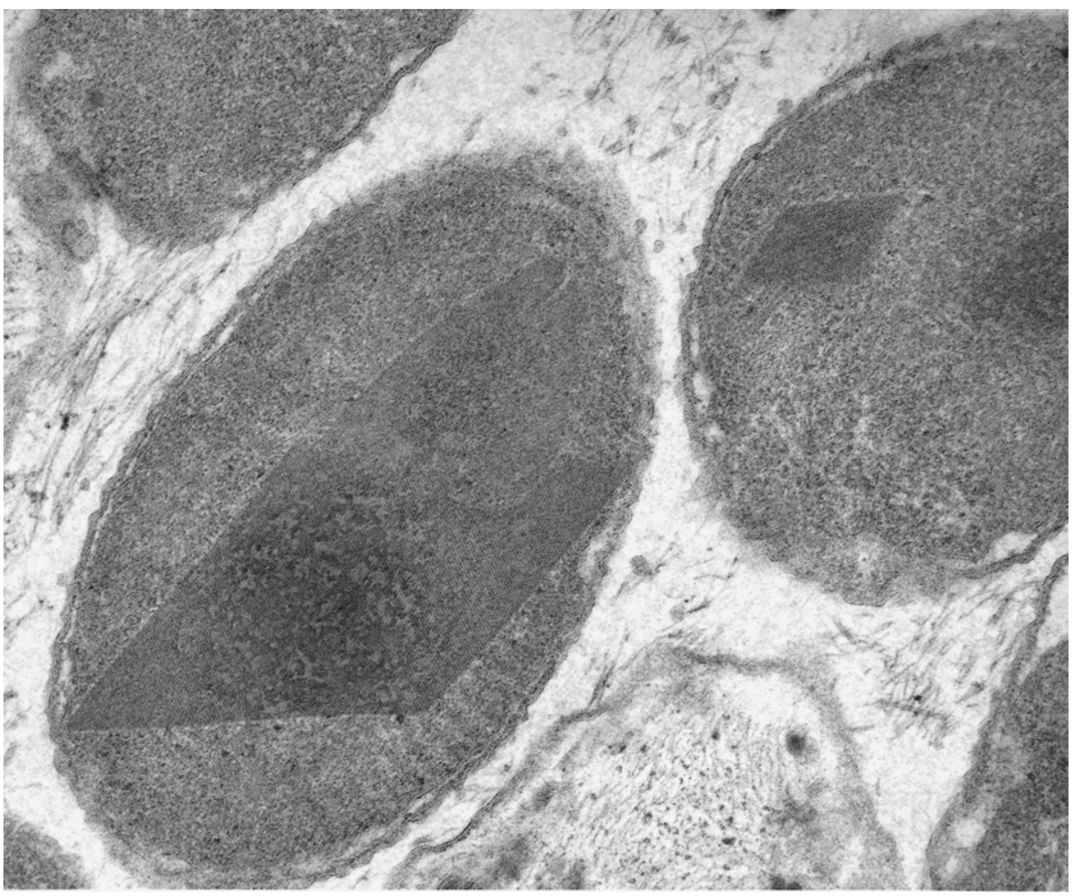

FIGURE BXII.γ.212. Protein inclusions in *X. nematophila*, showing a rhomboidal crystalline inclusion and an ovoid inclusion body.

1993). Phase I, but not phase II, cells have a peritrichous array of fimbriae with diameter of 6.4 nm, morphologically similar to the type I fimbriae of *E. coli* (Binnington and Brooks, 1993; Moureaux et al., 1995).

Phase I *Xenorhabdus* such as those isolated from the nematode associates or insects infected by the nematodes form convex, circular colonies with slightly irregular margins and a diameter of 1.5–2 mm after 4 d at 28°C; they also have a slightly granular appearance and, in some species, are pigmented (yellow, brown). These colonies adsorb dyes, such as bromothymol blue and neutral red, taking on intense coloration. Phase II variants generally form similar colonies but are flatter and wider (diameter 2.5–3.5 mm after 4 d at 28°C) and with lesser pigmentation; these colonies adsorb dyes only very weakly and no coloration is evident in 4-d colonies.

The major cellular fatty acids of *Xenorhabdus* are $C_{16:0}$, $C_{16:1}$, $C_{18:1}$, and $C_{17:0\ cyc}$, and the respiratory quinone system is ubiquinone-8 (Suzuki et al., 1990).

Xenorhabdus species are easily grown *in vitro* on a range of complex liquid and solid media and in minimal media supplemented with nicotinic acid, *p*-aminobenzoic acid, serine, tyrosine, and/or proline (Grimont et al., 1984b); nutrient agar is suitable for all strains. They are mesophilic; most grow between 15 and 30°C but strains growing at 4°C or at 40°C have been isolated.

On the basis of 16S rDNA sequence data, *Xenorhabdus* can be distinguished from its nearest phylogenetic neighbor, *Photorhabdus* (Fig. BXII.γ.213), by the sequence TTCG at positions 208–211 (*E. coli* numbering) of the 16S rDNA where *Photorhabdus* has a longer version (TGAAAG) (Szállás et al., 1997). DNA–DNA hybridization demonstrated the existence of a number of undescribed species in the genus (Fig. BXII.γ.214). Data have been recorded for some of the strains that would be assigned to new *Xenorhabdus* species (Boemare and Akhurst, 1988) but too few to warrant a decision on their taxonomic status; there are no 16S rDNA data for any of these strains.

Conjugation of plasmids from *E. coli* has been applied successfully for *X. nematophila* and *X. bovienii* (Smigielski and Akhurst, 1992; Francis et al. 1993; Forst and Nealson, 1996). In contrast, transformation of *Xenorhabdus* has not been generally successful. Although Xu et al. (1989) reported the transformation of the type strain of *X. nematophila* with a broad host-range vector, they and other workers have been unsuccessful with other strains of *X. nematophila* and other *Xenorhabdus* spp. The increase in transformation efficiency after the vector had been passed through *X. nematophila* suggested the presence of a restriction modification system. This suggestion was further supported by the demonstration that *Xenorhabdus* DNA is not easily digested by several common restriction enzymes (Akhurst et al., 1992). Endonuclease activity has subsequently been detected in a range of *Xenorhabdus* spp. (Akhurst et al., 1992).

Hypovirulent and avirulent mutants have been produced in *X. nematophila* by chemical and transposon mutagenesis (Xu et al., 1991; Dunphy, 1994). Francis et al. (1993) developed a transposon mutagenesis system for *X. bovienii* by constitutively expressing *lamB* on the surface of the bacterium, allowing them to be infected with lambda particles carrying the Tn10 transposon. This process produced various dye-binding, lipase, protease, hemolytic, and DNase mutants.

Couche et al. (1987) demonstrated the presence of one or two small plasmids (3.6–12 kb) in some, but not all, *X. nematophila* and *X. bovienii* strains. The plasmid profiles did not differ between phases I and II. Smigielski and Akhurst (1994) reported two megaplasmids (71.8 and 118.5 kb) as well as two additional plasmids (6.5 and 17 kb) in the A24 strain of *X. nematophila*. They also demonstrated that all strains of *X. nematophila*, *X. bovienii*, *X. beddingii*, and *X. poinarii* contained megaplasmids (48 to >680 kb) and that there were no differences in megaplasmid profile between phases I and II.

The presence of lysogenic phage in and production of bacteriocins by *X. nematophila* was demonstrated by Boemare et al. (1992). Lysis of both phases of *X. nematophila*, *X. bovienii*, and *X. beddingii* in response to mitomycin C or heat shock released complete and partial phages. In addition to inhibiting nonhost *Xenorhabdus*, the bacteriocins inhibited *P. luminescens*, *Proteus vulgaris*, and *Morganella morganii* but no other Gram-negative or Gram-positive bacteria tested, indicating that the bacteriocins act against closely related genera in contrast to the antibiotics produced by phase I variants that have a wide spectrum of activity. The *X. nematophila* bacteriocin xenorhabdicin was shown to consist of two major protein bands, corresponding to the sheath and core, and five minor bands; the phage head capsid had one major and two minor subunits (Thaler et al., 1995).

Antibiograms scored after 3 d at 28°C show that *Xenorhabdus* spp. are inhibited by streptomycin, neomycin, gentamicin, tetracycline, kanamycin, and colistin, but not penicillin. Most strains are resistant to ampicillin and cephaloridine and, to a lesser extent, furazolidone, whereas resistance to chloramphenicol is limited. Resistance to streptomycin, tetracycline, and kanamycin after selection has been demonstrated for *X. nematophila*.

Xenorhabdus spp. are insect pathogens only when delivered into the insect hemocoel, either by their nematode symbiont or by injection; they are not pathogenic when applied topically. Most are highly toxic for larvae of the greater wax moth, *Galleria mellonella*, with an LD_{50} of <20 cells (Akhurst and Dunphy, 1993). *X. poinarii* has very little pathogenicity for *G. mellonella*, (LD_{50} = 5000 cells) when injected alone, although it is highly pathogenic when co-injected with axenic *Steinernema glaseri*, its natural host (Akhurst, 1986b). *X. nematophila* produces an orally active toxin complex of the same family as those produced by *Photorhabdus*, *Serratia entomophila*, and *Yersinia pestis* (Glare and Hurst, 2002) and a smaller single unit toxin that is toxic by injection (East et al., 1998). Their toxicity varies between insects, with *X. nematophila* having an LD_{50} of about 500 for *Hyalophora cecropia* caterpillars (Götz et al., 1981) and no toxicity to maggots of the genus *Chironomus* (Götz and Boman, 1985). *Xenorhabdus* spp. do not have any demonstrable effects on vertebrates (Poinar and Thomas, 1967; Poinar et al., 1982; Obendorf et al. 1983).

Xenorhabdus species have been found only in the intestinal tract of infective-stage nematodes of the genus *Steinernema* (syn. *Neoaplectana*) and in insects killed by these nematodes. There is a high degree of specificity in these associations, with each nematode species being naturally associated with only one *Xenorhabdus* species (Akhurst, 1983a; Table BXII.γ.278). This specificity is determined by the ability of the nematode to retain the bacterium in its intestinal vesicle (Bird and Akhurst, 1983; Akhurst and Boemare, 1990). Although there have been reports of other bacteria being associated with *Steinernema* (Lysenko and Weiser, 1974; Mracek, 1977; Aguillera et al., 1993), closer examinations have always demonstrated that only *Xenorhabdus* have a specific association (Akhurst, 1982b; Bonifassi et al., 1999).

The infective stage nematodes act as vectors, transporting the bacteria into the insect via natural orifices (mouth, anus, spiracles) and then into the hemocoel. The infective (dauer) nematode, a third-stage juvenile with closed mouth and anus, recom-

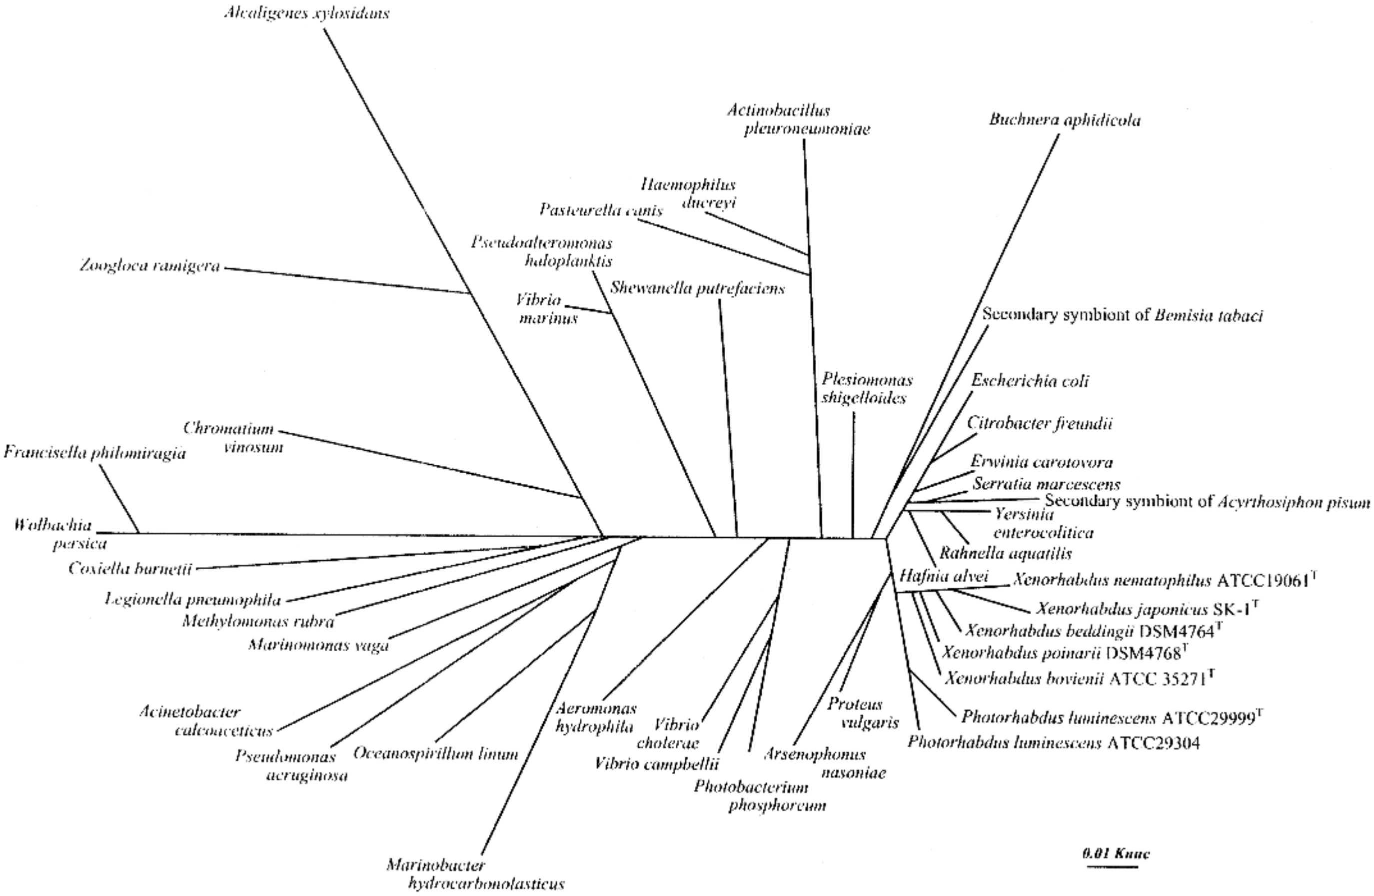

FIGURE BXII.γ.213. Phylogenetic tree showing the relationship of the genus *Xenorhabdus* to members of the *Gammaproteobacteria.* Note that since the publication of this figure, *Chromatium vinosum* has been transferred to the genus *Allochromatium* as *Allochromatium vinosum* (Imhoff et al., 1998b) and that *Vibrio marinus* has been transferred to the genus *Moritella* as *Moritella marina* (Urakawa et al., 1998, 1999b); in addition, the spelling of the species name *japonicus* has been corrected to *japonica* and that of *nematophilus* to *nematophila* (Euzéby and Boemare, 2000). FIGURE BXII.γ.214. DNA relatedness of 20 strains of bacterial symbionts of entomopathogenic nematodes (modified from Boemare et al., 1993), indicating that strains representing a number of undescribed species have been isolated. In addition, the spelling of the species name *nematophilus* has since been corrected to *nematophila.*

mences development in the hemocoel, releasing its symbiotic bacterium and an inhibitor of the inducible antibacterial enzymes (Poinar and Himsworth, 1967; Götz et al., 1981). As *Xenorhabdus* multiplies it provides essential nutrients for nematode maturation and reproduction (Poinar and Thomas, 1966) and produces antibiotics (Paul et al., 1981; Akhurst, 1982a; McInerney et al. 1991a, b; Li et al., 1996).

Xenorhabdus alternates between a nutrient rich (insect) and nutrient poor (nematode) existence. Forst et al. (1997) hypothesized that phase II may be induced by the nematode gut conditions and better adapted to the nutrient poor conditions of the intestinal vesicle of the nonfeeding nematode. However, this hypothesis does not account for the fact that the bacteria isolated from field-collected infective stage juveniles are inevitably phase I. Smigielski et al. (1994) found differences in the activity of respiratory enzymes of phases I and II that indicate the greater potential of phase II to survive in soil environments than phase I. The lack of a record of isolation of *Xenorhabdus* directly from soil may be due to its slow growth, lack of a suitable selective medium, and/or the difficulty of identifying phase II, which has few positive characters in most standard tests for identifying bacteria. However, Morgan et al. (1997) found that *X. nematophila* declined very quickly in river water and soil, becoming undetectable after 2 d and 7 d, respectively. Although the phase status

of *X. nematophila* used in that study was not specified, it seems likely that they used phase I. At this time, there is no satisfactory explanation of the ecological role of phase II.

Enrichment and Isolation Procedures

Xenorhabdus spp. generally grow well at 25–28°C on nutrient or similar agar (e.g., Luria-Bertani, trypticase soy), but best growth has been achieved with yeast extract-salts (YS; Dye, 1968) and medium X (Götz et al., 1981) agars. *Xenorhabdus* can be isolated from the infective-stage nematodes by the hanging drop technique or by maceration (Poinar and Thomas, 1966; Akhurst, 1980). For both methods, the infective juveniles must first be surface sterilized; this is readily achieved by immersing a small number of live infective-stage nematodes (<100), free of debris, in 0.1% merthiolate for 1 h at room temperature and then rinsing thoroughly in several changes of sterile water. In the hanging-drop technique, individual surface-sterilized infective juveniles are transferred to a drop of aseptically collected insect hemolymph on a coverslip that is then inverted over a cavity to prevent desiccation and incubated at 25°C until the nematodes commence development (1–3 d). At this time, they void their symbiotic bacteria, which can be subcultured from the hemolymph onto an agar medium (e.g., nutrient agar) 1 d later. A more rapid method involves the maceration of 50–100 surface-sterilized infective juveniles in a nutrient broth by means of a tissue homogenizer. The macerate should be plated onto an agar medium immediately (10–100 μl aliquots) and incubated at 28°C for 3 d. The inclusion of suitable controls to confirm that the surface-sterilization procedure has been effective is essential for both methods. *Xenorhabdus* can also be isolated by the less labor-intensive method of collecting hemolymph from an insect (e.g., *G. mellonella*) larva within 24 h of its death after infection by *Steinernema*. With this last method, bacteria other than *Xenorhabdus* may also be isolated; these bacteria may be carried into the host on the exterior of the nematodes or may be picked up into the hemolymph from the insect cuticle. Contamination by other bacteria can be minimized by burying the insect in clean, damp sand, adding a small number of nematodes to the surface of the sand and incubating at 20–25°C until one to five nematodes infect the insect. This last method is better suited to reisolation of a *Xenorhabdus* strain rather than to determining the identity of the bacteria specifically associated with a nematode species.

Maintenance Procedures

Storage in 20% glycerol at −70°C or below is very useful for long-term maintenance of *Xenorhabdus* cultures; they do not store well at −20°C. Short-term storage (less than 1 month) is best conducted at 10–15°C because survival on agar or in broth at 4°C is very poor, and when cultures are maintained at temperatures in excess of 15°C there is a significant risk of a proportion of the culture undergoing phase change.

Procedures for Testing Special Characters

All tests for phenotypic characterization of *Xenorhabdus* spp. should be conducted at 28°C.

Dye adsorption in most *Xenorhabdus* species can be tested on nutrient agar containing 0.0025% (w/v) bromothymol blue and 0.004% (w/v) triphenyltetrazolium chloride (NBTA; Akhurst, 1980). Dye-adsorbing phase I colonies will appear dark blue, while nonadsorbent phase II colonies will be red. As *X. poinarii* does not adsorb bromothymol blue, dye adsorption in this species can be assessed on MacConkey agar; adsorbing colonies are dark red (Akhurst, 1986b). Congo red (Francis et al., 1993) and some other dyes can also be used for most *Xenorhabdus* spp.

Insect pathogenicity is tested by injection of 100, 1000, and 10,000 cells (total count) from a 24-h broth culture into final instar *G. mellonella* larvae. The injected larvae should be placed on dry filter paper in Petri dishes and incubated at 25°C for 3 d. Most *Xenorhabdus* spp. will kill >50% at a dosage of 100 cells; all will kill >50% at 10,000 cells. The use of a less susceptible host (e.g., *Manduca sexta*) has enabled detection of differences in pathogenicity between the two phases of a strain (Volgyi et al., 1998).

Antibiotic production is tested by spot inoculating *Xenorhabdus* spp. onto nutrient agar and incubating at 28°C for 3 d. At this time the bacteria are killed by exposure to chloroform vapor for ~1 h. After the chloroform has evaporated from the agar, semisolid nutrient agar (0.5%) inoculated with a suitable indicator organism (*Micrococcus luteus* or another Gram-positive species) is poured to form a thin layer. After incubation at 28°C overnight, a halo of inhibition around antibiotic-producing colonies will be evident.

Differentiation of the genus *Xenorhabdus* from other genera

Xenorhabdus spp. are easily distinguished from other *Enterobacteriaceae* by the absence of catalase in the former and, with the exception of *Photorhabdus*, by their inability to reduce nitrate. The key characteristics for differentiating *Xenorhabdus* from its most closely related genera are shown in Table BXII.γ.279.

Taxonomic Comments

The first symbiotic bacterium isolated from entomopathogenic nematodes was described as a new species *Achromobacter nematophilus* (Poinar and Thomas, 1965). With the rejection of the genus *Achromobacter* (Hendrie et al., 1974), this new species could not be accommodated within any existing genus. Thomas and Poinar (1979) described a new genus, *Xenorhabdus*, to accommodate the bacterial symbionts of entomopathogenic nematodes as two species, *X. nematophila*, symbionts of the family *Steinernematidae*, and *"X. luminescens"*, associated with the *Heterorhabditidae*. These bacteria have low DNA–DNA relatedness (4%) to the type species of the type genus of the family *Enterobacteriaceae* (Farmer, 1984b) and lack nitrate reductase, which is positive for all other genera in the family. However, they do have the enterobacterial common antigen (Ramia et al., 1982), and phylogenetic analyses based on 16S rDNA (Suzuki et al., 1996; Brunel et al., 1997; Liu et al., 1997a; Szállás et al., 1997) confirm their relatedness to the *Enterobacteriaceae*.

From a phenotypic study of bacterial symbionts of the *Steinernematidae* and *Heterorhabditidae*, five groups were recognized

TABLE BXII.γ.279. Characteristics differentiating *Xenorhabdus*, *Photorhabdus*, and *Proteus*[a]

Characteristic	*Xenorhabdus*	*Photorhabdus*	*Proteus*

within the genus and the subdivision of *X. nematophila* into subspecies proposed (Akhurst, 1983b). A more comprehensive phenotypic study (Boemare and Akhurst, 1988) led to the elevation of the subspecies to species status, as *X. nematophila*, *X. bovienii*, *X. poinarii*, and *X. beddingii* (Akhurst and Boemare, 1988). *Xenorhabdus japonica*[1], symbiotically associated with *Steinernema kushidai*, was described later (Nishimura et al., 1994). DNA–DNA hybridization (Suzuki et al., 1990; Akhurst et al., 1996) and 16S rDNA (Suzuki et al., 1996; Brunel et al., 1997; Liu et al., 1997a; Szállás et al., 1997) analyses validated the inclusion of these five species in, and the exclusion of *P. luminescens* from, the genus.

DNA–DNA hybridization analysis indicates that there are more than the five *Xenorhabdus* species described to date (Fig. BXII.γ.214). Too few isolates of the other "species" have been characterized phenotypically to allow description of new species.

List of species of the genus Xenorhabdus

1. **Xenorhabdus nematophila** (Poinar and Thomas 1965) Thomas and Poinar 1979, 355[AL] (*Achromobacter nematophilus* Poinar and Thomas 1965, 249.)
ne.ma.to' phi.la. Modern entomological term n. *nematode;* Gr. adj. *philus* loving or having affinity for; M.L. adj. *nematophila* nematode-loving.

The species characteristics are listed in Tables BXII.γ.277 and BXII.γ.278. No isolates known to grow at temperatures in excess of 34°C. Neither phase is pigmented. Most isolates sensitive to furazolidone.

Only found associated with one species of nematode, *Steinernema carpocapsae*, but distributed globally.

The mol% G + C of the DNA is: 43–48 (Bd).

Type strain: ATCC19061, DSM 3370.

GenBank accession number (16S rRNA): D78009, X82251.

2. **Xenorhabdus beddingii** (Akhurst 1986a) Akhurst and Boemare 1993, 864[VP] (Effective publication: Akhurst and Boemare 1988, 1844) (*Xenorhabdus nematophilus* subsp. *beddingii* Akhurst 1986a, 456.)
bed.din' gi.i. M.L. gen. n. *beddingii* of Bedding, named for R.A. Bedding, who made significant contributions to the development of *Xenorhabdus*/*Steinernema* associations for insect pest control.

The species characteristics are listed in Tables BXII.γ.277 and BXII.γ.278. All isolates grow at 34°C, some at 38°C. Hydrolyses esculin. Inhibited by cephaloridine and ampicillin. The brown pigmentation is not strong. Phase I species is highly unstable, producing the very stable phase II.

Associated with two undescribed species of *Steinernema* from Australia, one of which may be *Steinernema longicaudum*, which was described from China.

The mol% G + C of the DNA is: 45.5–50 (Bd, HPLC).

Type strain: UQM 2871 (phase I of strain Q58), ATCC 49542, DSM 4764.

GenBank accession number (16S rRNA): D78006, X82254.

3. **Xenorhabdus bovienii** (Akhurst 1983b) Akhurst and Boemare 1993, 864[VP] (Effective publication: Akhurst and Boemare 1988, 1843) (*Xenorhabdus nematophilus* subsp. *bovienii* Akhurst 1983b, 45.)
bo.vi.en' i.i. M.L. gen. n. *bovienii* of Bovien, named for P. Bovien who first reported the presence of bacteria in the intestinal vesicle of a *Steinernema* species.

The species characteristics are listed in Tables BXII.γ.277 and BXII.γ.278. No growth at 34°C; some strains will grow at 5°C. Resistant to carbenicillin.

Associated with several species of entomopathogenic nematode (*Steinernema feltiae*, *Steinernema intermedium*, *Steinernema kraussei*, *Steinernema affine*) in temperate regions.

The mol% G + C of the DNA is: 44.3 (HPLC)–46.9 (Bd).

Type strain: UQM2210 (phase I of strain T228), ATCC 35271, DSM 4766.

GenBank accession number (16S rRNA): X82254, D78007.

4. **Xenorhabdus japonica** Nishimura, Hagiwara, Suzuki and Yamanaka 1995, 619[VP] (Effective publication: Nishimura, Hagiwara, Suzuki and Yamanaka 1994, 209.)
ja.po' ni.ca. M.L. adj. *japonica* of Japan.

The species characteristics are listed in Tables BXII.γ.277 and BXII.γ.278. Does not grow at 37°C. Arginine dihydrolase activity detected in phase II. Pigmentation is yellowish brown.

Only known to be associated with *Steinernema kushidai* in Japan.

The mol% G + C of the DNA is: 45.9 (HPLC).

Type strain: IAM 14265.

GenBank accession number (16S rRNA): D78008, Z76739.

5. **Xenorhabdus poinarii** (Akhurst 1983b) Akhurst and Boemare 1993, 864[VP] (Effective publication: Akhurst and Boemare 1988, 1843 (*Xenorhabdus nematophilus* subsp. *poinarii* Akhurst 1983b, 45.)
poi.nar' i.i. M.L. gen. n. *poinarii* , of Poinar, named for G.O. Poinar, Jr., who made major contributions to the understanding of entomopathogenic nematode/bacterial interactions.

The species characteristics are listed in Tables BXII.γ.277 and BXII.γ.278. This is the most heat tolerant *Xenorhabdus*, with all strains growing at 36°C and some at 40°C. The intensity of pigmentation in phase I varies from light to reddish brown. Antibiotic production by phase I and phase II is variable. Associated with *Steinernema glaseri* and *Steinernema cubanum* in the USA and Caribbean. The nematode/bacterium association does not appear to be as strong for

1. Euzéby and Boemare (2000) noted that *-rhabdus* has a feminine root and so species names for genera ending in *-rhabdus* should also be feminine.

this species as for other *Xenorhabdus*; its symbiosis may be more primitive. It is not pathogenic for greater wax moth (*Galleria mellonella*) larvae unless associated with its nematode partner.

The mol% G + C of the DNA is: 42.6 (HPLC)–49 (Bd).

Type strain: UQM 2216 (phase I of strain G), ATCC 35272, DSM 4768.

GenBank accession number (16S rRNA): D78010, X82253

Genus XLI. **Yersinia** Van Loghem 1944, 15[AL]

Edward J. Bottone, Hervé Bercovier and Henri H. Mollaret

Yer.si' ni.a. M.L. fem. n. *Yersinia* named for the French bacteriologist A.J.E. Yersin, who first isolated the causal organism of plague in 1894.

Straight rods to coccobacilli, 0.5–0.8 × 1–3 μm. Endospores are not formed. Capsules are not present, but an envelope occurs in *Y. pestis* strains grown at 37°C and in cells from clinical sources. Gram negative, **nonmotile at 37°C, but motile with peritrichous flagella when grown below 30°C, except for *Y. pestis*, which is always nonmotile**. Growth occurs on ordinary bacteriological media. Colonies of yersiniae are translucent to opaque, 0.1–1.0 mm in diameter after 24 h. Optimum growth temperature, 28–29°C. Facultatively anaerobic, having both a respiratory and a fermentative type of metabolism. Oxidase negative. Catalase positive. Nitrate is reduced to nitrite with a few exceptions in specific biovars. D-glucose and other carbohydrates are fermented with **acid production but little or no gas**. **Phenotypic characteristics are often temperature dependent, and usually more characteristics are expressed by cultures incubated at 25–29°C than at 35–37°C.** The enterobacterial common antigen is present in all species investigated. Widely distributed in nature with some species adapted to specific animal hosts and humans. Several species are pathogenic for humans and animals including *Y. pestis*, the causative agent of plague. A significant cause of food-borne and waterborne disease. Belongs to the *Gammaproteobacteria*.

The mol% G + C of the DNA is: 46–50.

Type species: **Yersinia pestis** (Lehmann and Neumann 1896) Van Loghem 1944, 15 (*Bacterium pestis* Lehmann and Neumann 1896, 194; *Yersinia pseudotuberculosis* subsp. *pestis* Bercovier, Mollaret, Alonso, Brault, Fanning, Steigerwalt and Brenner 1981a, 383.)

Further descriptive information

Cells of *Yersinia* species are small, coccoid-shaped Gram-negative bacilli that resemble cells of *Pasteurellaceae* rather than cells of *Enterobacteriaceae*. Pleomorphism occurs depending on the type of medium used and the temperature of incubation. Rods, coccobacilli, and small chains of four to five elements (especially in liquid media) can occur. Gram, Giemsa, or Wayson-stained smears reveal a more pronounced tendency to bipolar staining in *Y. pestis* than in the other species. Spores or specific inclusions are not formed. No definite capsule occurs, but *Y. pestis* displays a carbohydrate-protein envelope termed capsular antigen or fraction I (F-1) when cultured at 37°C (Burrows, 1963), or in direct smears taken from infected hosts (mice, guinea pigs, humans). L forms have been described for *Y. enterocolitica* (Pease, 1979).

Yersinia species are nonmotile after growth at 37°C but motile at 22–29°C, except *Y. pestis*, which is nonmotile irrespective of incubation temperatures. Fresh isolates of *Y. enterocolitica* and *Y. pseudotuberculosis* may require a few subcultures to express their motility. Motile cells have 2–15 peritrichous flagella characterized by a long wavelength (Nilehn, 1969).

Yersinias do not differ from other *Enterobacteriaceae* in their fine structure and overall cell wall composition. Lipopolysaccharides (O antigens) have been isolated and characterized (Davies, 1958; Rische et al., 1973). The whole-cell lipid composition of all *Yersinia* species investigated exhibits a pattern shared with other *Enterobacteriaceae* (Tornabene, 1973; Jantzen and Lassen, 1980). *Y. pestis* lipopolysaccharide has core components in common with other *Enterobacteriaceae* but lacks extended O-group side chains (Perry and Fetherston, 1997).

Placement of the genus *Yersinia* within the *Enterobacteriaceae* family is supported by both biochemical and DNA–DNA relatedness studies. Further studies (Ahmad et al., 1990) comparing rDNA sequence analysis to clustering based on aromatic amino acid synthesis placed the genus *Yersinia* in one of three "enteroclusters" along with *Cedecea*, *Edwardsiella*, *Hafnia*, *Kluyvera*, *Proteus*, *Providencia*, and *Morganella*. Sequence analysis of the 16S rRNA gene performed by Ibrahim and colleagues (1993) of representatives of 10 of the 11 *Yersinia* species reveal that yersiniae form a coherent cluster within the *Gammaproteobacteria* with sequence similarities ranging from 96.9–99.8%. Within the *Gammaproteobacteria* the closest relative is *Hafnia alvei* (96.5% sequence similarity).

Intragenerically, phylogenetic analysis disclosed five sublines, with *Y. enterocolitica*, *Y. rohdei*, and *Y. ruckeri* forming separate sublines. A separate subline was formed by *Y. pestis*, *Y. pseudotuberculosis*, and *Y. kristensenii*, while *Y. mollaretii*, *Y. intermedia*, *Y. bercovieri*, *Y. aldovae*, and *Y. kristensenii* formed a fifth subline.

Yersinia species grow on nutrient agar without enrichment. A small colony diameter differentiates yersiniae from all other *Enterobacteriaceae*. After incubation for 24–30 h at 30°C or 37°C, *Y. pestis* forms minute colonies (0.1 mm) that can be discerned only with difficulty by the naked eye. After 48 h their diameter increases to 1.0–1.5 mm. The colonies are slightly opaque, butyrous, smooth, round, and have somewhat irregular edges. The use of enriched media (serum, blood, yeast extract) does not dramatically improve growth, and after 48 h the colony sizes are similar to those found on nutrient agar. All other *Yersinia* species grown on nutrient agar at 25–37°C produce visible colonies in 24 h. The colonies reach a diameter of 1.0–1.5 mm after 24–30 h, and 2.0–3.0 mm after 48 h. After 18 h they are translucent, smooth, and round with irregular edges, but after 48 h the centers become elevated and the edges become more regular, producing a "Chinese hat" shape. *Y. pestis* colonies may appear slightly mucoid. When cultured for 48 h, all *Yersinia* species dissociate into small (0.5 mm) and large (2 mm) colonies. This phenomenon appears to depend on the medium used (Bercovier et al., 1979).

Growth is moderate in liquid media: incubation of *Yersinia* for 48 h will yield the same turbidity that occurs in 18 h with other *Enterobacteriaceae*. When grown in nutrient broth, clumps of *Y.*

pestis cells adhere to the side of the tube, which slowly forms a deposit at the bottom of the tube while the supernatant remains relatively clear; this is followed by the appearance of a pellicle, which in turn disintegrates to form flocculent masses and a larger deposit. This phenomenon is attenuated in peptone water. *Y. pseudotuberculosis* occasionally grows in a manner similar to that of *Y. pestis*. All other *Yersinia* species give uniform turbidity in nutrient broth and in peptone water.

Y. pestis and *Y. pseudotuberculosis* give variable growth responses on MacConkey agar. All other species grow well on this medium, with colonies reaching a size similar to that observed on nutrient agar. On Salmonella–Shigella agar incubated at 25°C, *Y. pestis* hardly grows at all, whereas all the other species produce pinpoint colonies in 24–30 h. When incubated on this medium at 37°C, *Y. enterocolitica* is only partially inhibited, whereas all other species are severely inhibited (Nilehn, 1969; Bottone, 1977; Bercovier et al., 1979).

All *Yersinia* species except *Y. pestis* can grow at 25°C on synthetic mineral-salt media with various carbohydrates as the energy source (Burrows and Gillett, 1966; Bercovier et al., 1979). *Y. pestis* requires L-methionine, L-isoleucine, L-valine, and L-phenylalanine, and or L-threonine for growth. When incubated at 37°C on synthetic mineral-salt media all *Yersinia* species become auxotrophic, and the addition of biotin and thiamine, and pantothenate and glutamic acid for *Y. pestis*, is necessary to promote growth (Burrows and Gillett, 1966; Brubaker, 1991). The growth of *Y. pestis* on such media is further enhanced by the addition of a reducing agent, and by incubation in a CO_2-enriched atmosphere (Brubaker, 1991). Virulent strains of *Y. pestis* require Ca^{2+} or ATP for growth at 37°C but not at 25°C (Zahorchak et al., 1979). This temperature-dependent requirement for Ca^{2+}, mediated by the Lcr plasmid, has also been described for virulent strains of *Y. pseudotuberculosis* and *Y. enterocolitica*.

The growth range is 4–42°C, with an optimum temperature of 28–29°C. *Y. pestis* and *Y. pseudotuberculosis* tolerate a pH range of 5.0–9.6; other *Yersinia* species can grow in a pH range of 4.0–10.0. The optimum pH for all species is 7.2–7.4. *Yersinia* species can grow in peptone water without the addition of NaCl. *Y. pestis* and *Y. pseudotuberculosis* tolerate up to 3.5% NaCl, and the other species can tolerate up to 5% NaCl. *Y. pseudotuberculosis*, but not *Y. enterocolitica*, which lacks tellurite reductase, is the only species that grows well on media containing 0.06% tellurite (Brzin, 1968).

Yersinia species do not differ significantly from other *Enterobacteriaceae* in their general metabolism (Brubaker, 1991) (Table BXII.γ.280). They produce acid during fermentation of D-glucose. *Y. enterocolitica*, *Y. frederiksenii*, and *Y. intermedia* produce acetoin (positive Voges–Proskauer test) when incubated at 28°C, whereas this characteristic is variable for *Y. ruckeri* and is absent in *Y. pestis* and *Y. pseudotuberculosis*. No *Yersinia* species produces acetoin at 37°C (Table BXII.γ.281).

The main physiological and biochemical characteristics of the various *Yersinia* species are given in Table BXII.γ.282. *Yersinia* ferment carbohydrates usually without gas production, a characteristic that is constant for *Y. pestis* and *Y. pseudotuberculosis*, but other species may produce a few bubbles after 2–3 days at 28°C. Because the optimum growth temperature of yersiniae is 28–29°C, some biochemical activities are often temperature-dependent (cellobiose and raffinose fermentation, ornithine decarboxylase, ONPG (*o*-nitrophenyl-β-D-galactopyranoside) hydrolysis, indole production, and the Voges–Proskauer reaction) and are more constantly expressed at 28°C rather than at 37°C. All species except *Y. intermedia* reduce nitrate to nitrite by a type B nitrate reductase; *Y. intermedia* strains have either a type A nitrate reductase, like most *Enterobacteriaceae*, or a type B reductase. ONPG activity of yersiniae does not correspond to a true β-galactosidase, but only to an ONPG-ase (Le Minor and Coynault, 1976). In addition to the characteristics given in Tables BXII.γ.281 and BXII.γ.282, *Yersinia* species are able to attack polypectate in 5–7 days and starch in 3–7 days. Yersiniae are neither hemolytic nor proteolytic, except *Y. ruckeri*, which liquefies gelatin, and some strains of *Y. pestis*, which have fibrinolytic and coagulase activity linked to the production of Pesticin 1. Plasminogen activator coagulase activity and pesticinogeny are plasmid (pPCD1) encoded. Lecithinase activity in *Y. enterocolitica* is strain-dependent. *Y. pseudotuberculosis*, *Y. enterocolitica*, and *Y. ruckeri* strains have a lipase that is active on corn oil, but only *Y. intermedia*, *Y. frederiksenii*, and *Y. enterocolitica* biovar I express a lipase-esterase that is active on Tween 80.

Transformation of auxotrophic strains of *Y. enterocolitica* by prototrophic strains using the Juni-Janik technique has been reported (Callahan and Koroma, 1979). F lac+ episomes from *E. coli* have been transferred to *Y. pestis* (Martin and Jacob, 1962), to *Y. pseudotuberculosis* (Lawton et al., 1968b), and to *Y. enterocolitica* (Cornelis and Colson, 1975), but usually with a low frequency (10^{-4}–10^{-6}) . This has allowed chromosomal mapping of *Y. pseudotuberculosis* (Lawton and Stull, 1971; McMahon, 1973). Gene transfer by conjugation between *Y. pseudotuberculosis* and *Y. pestis* has also been demonstrated (Lawton et al., 1968a).

R factors have been transferred to *Y. pestis* and *Y. pseudotuberculosis* (Ginoza and Matney, 1963) and to *Y. enterocolitica* (Knapp and Lebek, 1967). Wild strains of *Yersinia* carrying R plasmids (Cornelis et al., 1973; Kanazawa and Ikemura, 1979) appear to be rare. This could be explained, at least for *Y. enterocolitica*, by the presence of a restriction-modification system (Cornelis and Colson, 1975). A self-transmissible plasmid coding for lactose fermentation has been described in *Y. enterocolitica* (Cornelis et al., 1976). This plasmid is freely transmissible between strains of *Y. enterocolitica* and *E. coli*.

Other plasmids related to various virulence tests (Ca^{2+} dependency, autoagglutination, lethality for mice and gerbils, Sereny test) have been demonstrated in *Y. pestis* (Ferber and Brubaker, 1981; Brubaker, 1991), *Y. pseudotuberculosis* (Gemski et al., 1980b), and *Y. enterocolitica* (Gemski et al., 1980a; Zink et al., 1980). These plasmids of 40–48 MDa molecular weight constitute a family of related plasmids (Ben-Gurion and Shafferman, 1981; Portnoy et al., 1981). *Y. pestis* and *Y. pseudotuberculosis* have never been found to be lysogenic, whereas of 1252 strains of *Y. enterocolitica* studied, 86.4% were lysogenic when grown at 25°C but not at 37°C (Nicolle et al., 1973). Phages active on *Y. pestis* and *Y. pseudotuberculosis* have been described (Gunnison et al., 1951; Girard, 1953), but they are not host-specific and are used only for presumptive bacteriological diagnosis. Coliphages T2, T3, and T7 are also active on *Y. pseudotuberculosis* and *Y. pestis* (Hertman, 1964). A phage typing system, useful in epidemiological investigations has been developed for *Y. enterocolitica* (Nicolle et al., 1973): strains of *Y. enterocolitica* serogroup 0:3 are associated with phagovar VIII in Europe, IXa in the Republic of South Africa, and lXb in Canada and the United States (Bottone, 1997).

Strains of *Y. pestis* produce a bacteriocin active on *Y. pseudotuberculosis* (Ben-Gurion and Hertman, 1958). This was named Pesticin I by Brubaker and Surgalla (1962) after they detected a second bacteriocin (Pesticin 11) that was produced by *Y. pestis* and *Y. pseudotuberculosis*. Pesticin I has a narrow host range, being

active against a few strains of *E. coli*, serogroup IA and IB *Y. pseudotuberculosis* (Burrows, 1963), and serogroup 0:8 *Y. enterocolitica* (Brubaker, 1991). *Y. pestis* strains that produce Pesticin I also elaborate a fibrinolytic factor and a coagulase (Brubaker, 1972). A bacteriocin-like activity associated with the presence of phage tails has been described in *Y. enterocolitica* (Nicolle et al., 1973). *Y. intermedia* produces a bacteriocin-like substance at 25°C but not at 37°C that is active on certain strains of *Y. enterocolitica*, *Y. intermedia*, *Y. frederiksenii*, and *Y. kristensenii* (Bottone et al., 1979). Cafferkey et al. (1989) have shown that bacteriocin production by "avirulent" strains of serogroup 0:3 occurs at both 25°C and at 37°C and is active against isolates of serogroups 0:3, and single strains tested of 0:8 and 0:9 irrespective of the presence of the virulence plasmid.

The antigenic structure of *Yersinia* species is complex, but antigens are shared by *Y. pestis*, *Y. pseudotuberculosis*, and *Y. enterocolitica*. The common enterobacterial antigen has been found in these species (Le Minor et al., 1972; Maeland and Digranes, 1975). The fraction I envelope antigen (FI) of *Y. pestis* is best produced when cultures are incubated at 37°C on protein-rich media (Fox and Higuchi, 1958). This antigen, a large gel-like capsule or envelope, is heat labile (10 min at 100°C), water soluble, and dissociates during growth into a glycoprotein (FIA) and a carbohydrate-free protein (FIB). Passive hemagglutination with FI antigen is used for serologic surveys in plague foci. The presence of this antigen has also been demonstrated in *Y. pseudotuberculosis* (Quan et al., 1965). V and W antigens expressed by virulent strains of *Y. pestis* cultivated at 37°C appear to be related to the presence of a 45 MDa plasmid (Ben-Gurion and Shafferman, 1981; Ferber and Brubaker, 1981). Production of plasmid-mediated V and W antigens has also been described in *Y. pseudotuberculosis* (Gemski et al., 1980b) and in *Y. enterocolitica* (Gemski et al., 1980a). The somatic antigen of *Y. pestis* is rough (R antigen) and therefore no serogroups have been described in this species. This R antigen is also present in *Y. pseudotuberculosis* (Thal and Knapp, 1971). In addition, *Y. pestis* and *Y. pseudotuberculosis* share at least 11 of 18 antigens (Lawton et al., 1960). *Y. pestis* and *Y. enterocolitica* express common protein antigens (Barber and Eylan, 1976). The antigenic scheme for *Y. pseudotuberculosis* (Thal and Knapp, 1971) comprises eight main thermostable serogroups (I to VIII) with nine subtypes (IA, IB; IIA, IIB, IIC; III; IVA, IVB; VA, VB; VI; VII; VIII), and five thermolabile flagellar H antigens (a–e). Antigenic relationships have been demonstrated between *Y. pseudotuberculosis* (serogroups 11, IV, IVA, and VI) and *Salmonella* serogroups B and D, *E. coli* serogroups 017, 055, and 077, and *Enterobacter cloacae* (Knapp, 1968; Mair and Fox, 1973).

Wauters et al. (1972) initially described 34 different O antigen and 20 H antigen serogroups in *Y. enterocolitica*. This classification included some serogroups defined by strains belonging to *Y. intermedia* (O:17) and *Y. kristensenii* (O:11, 0:12, 0:28). Wauters et al. (1991) subsequently expanded the O and H antigenic schema to include approximately 60 serogroups. Serogroup expansion has also shown sharing of antigens between pathogenic and nonpathogenic *Y. enterocolitica* and *Y. bercovieri* (O:8), *Y. frederiksenii* (O:3), and *Y. mollaretii* (O:3). Nevertheless, serogrouping in conjunction with biogrouping (Table BXII.γ.283), is a useful epidemiological marker. Cross-reactions occur between *Y. enterocolitica* serogroup O:9 and *Brucella* species (Hurvell and Lindberg, 1973; Corbel, 1975).

Yersinia species are susceptible *in vitro* to the following anti-

microbial agents: tetracycline, chloramphenicol, aminoglycosides (amikacin, streptomycin, gentamicin, kanamycin, and neomycin), sulfonamides (alone or in combination with trimethoprim), imipenem, aztreonam, and fluoroquinilones (Hoogkamp-Korstanje, 1987; Bonacorsi et al., 1994). They are variably susceptible to colistin and are resistant to erythromycin and novobiocin. *Y. pestis* and *Y. pseudotuberculosis* are usually susceptible to β-lactam antibiotics, but their susceptibility to penicillin is in the range of susceptible to intermediate. Resistance to ampicillin (Borowski and Zaremba, 1973) and to streptomycin (Kanazawa and Ikemura, 1979) has been described for *Y. pseudotuberculosis*, *Y. enterocolitica*, and *Y. intermedia* (Bottone, 1977). *Y. frederiksenii* and *Y. kristensenii* are resistant to penicillin and slightly susceptible or resistant to other β-lactam antibiotics (ampicillin, carbenicillin, cephalothin) (Bercovier et al., 1979). The level of resistance is strain dependent (Zaremba and Aldová, 1979) and temperature dependent (Chester and Stotzky, 1976). Antibiotic susceptibility patterns of *Y. enterocolitica* are serogroup specific. *Y. enterocolitica* strains produce both a constitutive β-lactamase (active on ampicillin, carbenicillin, penicillin, and cephalosporins) and an inducible β-lactamase active only on cephalosporins and penicillin (Cornelis and Abraham, 1975). *Y. enterocolitica* strains that are resistant to tetracycline, chloramphenicol, streptomycin, and kanamycin have been reported (Zaremba and Aldová, 1979). Newer β-lactam antibiotics such as ceftriaxone, ceftazidime, cefotaxime, and moxalactam have excellent activity against *Y. enterocolitica*, as do imipenem and aztreonam (Hornstein et al., 1985).

Y. pestis is the causative agent of plague. Plague is primarily a disease of wild rodents. *Y. pestis* is transmitted among wild rodents by flea bites or ingestion of contaminated animal tissues (Butler, 1983). In fleas, the bacterium multiplies and blocks the esophagus and the pharynx. The fleas regurgitate the bacteria when they take their next blood meal and transmit *Y. pestis* to humans if no other hosts are available. Infective flea bites produce the typical bubonic form of plague within 2–8 d. *Y. pestis* multiplies intracellularly in macrophages and extracellularly and proceeds through the lymphatic system. The lymph nodes near the flea

[a]All *Yersinia* spp. are fermentative; negative for H_2S, oxidase, arginine dihydrolase, phenylalanine deaminase, malonate, dulcitol, DNase (25°C), and pigmentation; all are positive for mannitol and mannose. Motile species have peritrichous flagella, and motility is more pronounced at temperatures less than or equal to 30°C. Except for delayed reactions in some *Y. ruckeri*, all species are negative for gelatin hydrolase and lysine decarboxylase.

bite are the first to become inflamed, enlarged, and painful, and constitute the bubo. As the evolution of the infection is usually rapid with massive growth of *Y. pestis* in the blood, characteristic lesions are not found in the spleen or liver at autopsy. Untreated, the disease evolves in 5–10 d to profound septicemia in which *Y. pestis* may be seen in peripheral blood smears (Mann et al., 1984). Secondary pneumonia may result from hematogenous spread. From the latter, primary pneumonic plague can spread

[b]Biogroup 1B is comprised mainly of strains isolated in the United States.

from person to person or from animals to humans by means of droplets. Both bubonic and pneumonic plague have been transmitted to humans by the domestic cat—bubonic through a scratch and bite from an infected cat (Thornton et al., 1975; Weniger et al., 1984), and pneumonic through face-to-face exposure to a cat with pneumonic plague (Werner et al., 1984; Doll et al., 1994). In this clinical form, death generally occurs in less than 4 d. Pestis minor cases, in which the bacteria remain self-limited in buboes followed by self-cures have been described in endemic plague areas (Pollitzer, 1954).

Virulence of *Y. pestis* is associated with several factors (Surgalla et al., 1968; Perry and Fetherston, 1997). Among these are synthesis of the fraction I (FI) gel-like antiphagocytic capsule or surface antigen, VW antigens (associated with Ca^{2+} dependency for growth on magnesium oxalate medium, autoagglutination in broth cultures at 37°C, pigment production (incorporation of Congo red dye or hemin into cell surfaces, which results in dark greenish-brown or red colonies at 26°C but not at 37°C), presence of siderophore (yersiniabactin) iron-acquisition system, pH6 antigen, a fibrillar adhesin surface structure that may facilitate entry into macrophages (Straley, 1993) and is synthesized in host macrophage lysosomes (Lindler and Tall, 1993), and serum resistance necessary for growth in blood and transmission between insect vector and mammalian hosts. Pesticin production (Pst plasmid) is necessary for dissemination of *Y. pestis* from peripheral sites of inoculation; Pst is a 9.5-kb plasmid that also encodes plasminogen activator, a fibrinolysin, coagulase activity, which may be limited to rabbit plasma (Brubaker, 1991), and murine toxin, a 6-adrenergic antagonist that is highly lethal for mice and rats, causing circulatory collapse. LD_{50} dose for mice inoculated with strains expressing the aforementioned virulence factors is 1–10 organisms. Avirulent strains of *Y. pestis* never produce VW antigens except in the case of the vaccine strain EV76, whose attenuated virulence has resulted from a mutation in its iron metabolism. Virulent strains and the EV76 strain harbor a 45-MDa plasmid. In contrast to the VW antigens, the lack of any of the other virulence factors does not completely abolish the virulence of *Y. pestis* strains.

Y. pseudotuberculosis is responsible for epizootics in nearly all animal species, especially in rodents and birds. Animals are usually contaminated by the oral route and, after 1–2 weeks of incubation, the bacteria are found in mesenteric lymph nodes. The main symptoms are mesenteric adenitis and chronic diarrhea. Infection evolves either in self-cure, or in fatal septicemia. *Y. pseudotuberculosis* is an intracellular parasite and, like *Y. pestis*, reaches the lymphatic system. At autopsy, caseous lesions are found in Peyer's patches, mesenteric lymph nodes, the spleen, and the liver. Humans orally contaminated by *Y. pseudotuberculosis* develop either a mesenteric adenitis, which simulates acute appendicitis, or, in the compromised host, a severe septicemia. *Y. pestis* and *Y. pseudotuberculosis* share a common 70-kb plasmid low calcium response (LCR) that encodes for calcium dependency and four outer membrane proteins, and the V and W antigens. *Y. pseudotuberculosis* chromosomally controlled virulence factors include the outer membrane protein invasin, which promotes host cell penetration (Isberg and Falkow, 1985).

Y. enterocolitica has been recognized as pathogenic for chinchillas, hares, monkeys, and humans. The pathogenicity for animals is similar to that of *Y. pseudotuberculosis.* In humans the most common presentation is acute enteritis in children. Concurrent mesenteric lymphadenitis and terminal ileitis simulating appendicitis may also be present. In young adults, acute terminal ileitis and mesenteric lymphadenitis appear to be more common. The extent of gastrointestinal tract pathology depends on the serogroup of the invading strain and age and underlying status of the host. In adults secondary clinical forms of infection include arthritis and erythema nodosum. Septicemia with metastatic abscesses is a rarer complication and is usually associated with immunosuppression or occurs in the setting of iron overload in individuals receiving the iron chelator desferrioxamine (Robins-Browne and Pipic, 1985). Septicemia and profound shock has been associated with transfusion of *Y. enterocolitica* contaminated blood (reviewed by Bottone, 1999). Secondary immunologically mediated sequelae include arthritis and erythema nodosum. Arthritis is closely associated with the presence of the histocompatibility antigen HLA-27 (Dequeker et al., 1980), especially among Scandinavians, and *Y. enterocolitica* serogroup 0:3 biotype 4, phage type 8, and serogroup 0:9 infections. Production of a heat-stable enterotoxin (ST) resembling *E. coli* ST (Okamoto et al., 1981) has been demonstrated *in vitro* (Pai and Mors, 1978), but its role in pathogenicity is not clear: *Y. enterocolitica* strains do not produce ST when incubated *in vitro* at temperature above 30°C, and direct proof of ST production *in vivo* has not been reported.

Virulent plasmid-containing strains of *Y. pestis*, *Y. pseudotuberculosis*, and *Y. enterocolitica* rapidly become avirulent when grown at 37°C, which results in the loss of the virulence plasmid. Cross-immunity among these three species has been demonstrated

(Thal, 1973; Alonso et al., 1978). Human chemoprophylaxis with streptomycin (drug of choice), tetracycline, and chloramphenicol; vaccination; and the spreading of insecticides and rodenticides are the suggested measures for controlling plague. For persons exposed to *Y. pestis*, tetracycline, doxycyline, and trimethoprim-sulfamethoxazole are recommended (Poland, 1989).

The pathogenicity of *Y. intermedia*, *Y. kristensenii*, *Y. frederiksenii*, *Y. bercovieri*, and *Y. mollaretii* in humans and animals is not clearly established. They appear more like opportunistic pathogens than true pathogens (Bercovier et al., 1978; Wauters et al., 1988; Bottone, 1997). ST-producing strains of these three species have been described (Kapperud, 1980), but their clinical significance is still unknown. *Y. ruckeri* is a fish pathogen responsible for red mouth disease, especially in rainbow trout. An inflammation of the mouth and the throat is the main characteristic of the disease, which is enzootic (Rucker, 1966). The bacterium is usually isolated from the kidneys of fish undergoing a systemic infection.

Epidemiology The geographical distribution of *Y. pestis* is widespread, and the organism has been isolated from all continents except Australia and Antarctica. Plague is enzootic in Africa (Central, East, and South Africa), in North and South America, certain regions of Asia (Southeast Asia, Mongolia), and the former USSR, India, and southwestern United States and the Pacific coastal area (Perry and Fetherston, 1997). Between epidemics, *Y. pestis* remains localized in enzootic or maintenance hosts (Butler, 1983) and has been isolated from more than a hundred different naturally infected species of rodents, but rarely from predatory animals (carnivores and birds, the latter being resistant to the infection). The spread of plague is usually accomplished by the epizootic cycle of rodents to fleas and fleas to rodents. The reservoir for *Y. pestis* is soil contaminated by infected dead fleas and rodents in which the microorganism survives for months in deep rodent burrows.

Rodents coming from noninfected areas become infected when they dig burrows in previously contaminated areas (Mollaret et al., 1963). This cycle constitutes "sylvatic plague". When urban rodents come in contact with rural rodents, *Y. pestis* can spread between rodents and to humans through flea bites. The epidemiology of plague is thus linked to the ecology of both fleas and rodents.

Y. pseudotuberculosis is distributed worldwide. It has been found in numerous animal species, especially rodents and birds, in soil, and in humans (Wetzler, 1970). In Japan, cats and dogs have been associated with human cases (Fukushima et al., 1989). Wild animals, which are often asymptomatic carriers, are considered the reservoir of the bacteria. Humans and animals are contaminated orally either by direct contact with sick or asymptomatic animals or through food contaminated by the excretions of these animals. The incidence of *Y. pseudotuberculosis* infection varies with the season and is highest during colder months. *Yersinia* species multiply at 4°C and therefore have a selective advantage over other bacteria at low temperatures; this explains why *Y. pseudotuberculosis*, *Y. enterocolitica*, *Y. frederiksenii*, and *Y. kristensenii* are more frequently isolated from the environment during cold rather than hot seasons. Human and animal infections follow this seasonal distribution as well.

Y. enterocolitica has been isolated from a wide variety of sources (live and inanimate) in every country in which it has been sought and probably has a worldwide distribution (Mollaret et al., 1979). As shown in Table BXII.γ.284, biovar IA strains are ubiquitous, having been found in a wide range of animal and environmental sources (including foods), whereas other biovars or serogroups are frequently associated with a specific host (Bercovier et al., 1980a): biovar 5 strains have been isolated mainly from hares in Europe; biovar 4, serogroup 0:3 strains are responsible for most human gastrointestinal infections in Europe, Canada, and the Republic of South Africa, and recently in the United States as well (Bottone et al., 1987; Ostroff, 1995). Serogroup 0:8, heretofore the most frequently isolated *Y. enterocolitica* strain in the United States, has decreased in frequency in the United States, and is only sporadically reported in other parts of the world (Ostroff, 1995). Serogroup 0:9 strains are the second most common *Y. enterocolitica* isolates in Europe and Japan.

Y. intermedia and *Y. frederiksenii* have been identified in Europe, the United States, Australia and New Zealand, Israel, and Japan. These two species have been isolated mainly from fresh water and foods and only rarely from nonirrigated soil, humans or animals other than fish (Kapperud, 1977; Bercovier et al., 1978; Brenner et al., 1980a; Ursing et al., 1980a). *Y. kristensenii* has been found in Europe, the United States, Japan, and Australia. Strains of this species have been isolated mainly from soil, foods, and asymptomatic animals; isolates from other environmental sources and from human infection are rare (Bottone and Robin, 1977; Bercovier et al., 1980b). *Y. bercovieri* has been recovered from terrestrial ecosystems (Bercovier et al., 1978), while *Y. mollaretii* has been isolated from human stool specimens, most raw vegetables, soil, and drinking water (Fukushima, 1985; Kaneko and Maruyama, 1987). Evidence of human disease potential for either *Y. bercovieri* or *Y. mollaretii* are lacking.

Y. ruckeri, which is taxonomically tentative in the genus *Yersinia*, has been encountered mainly in the United States and Canada as a natural component of fresh water ecosystems. *Y. ruckeri* causes enteric red mouth disease of salmon and fish when fish are exposed to large numbers of bacteria (Ross et al., 1966). The disease is usually enzootic and occasionally epizootic in fish hatcheries especially under conditions of stress or poor environmental factors (Stevenson, 1997). Five serovars and two biotypes of *Y. ruckeri* have been identified. Serovar I strains are usually D-sorbitol positive, while serovar 2 isolates are usually D-sorbitol negative (Stevenson and Daly, 1982; Stevenson and Airdrie, 1984). A 36-MDa transferable plasmid encoding resistance to tetracycline and sulfonamides has been identified in some *Y. ruckeri* strains (DeGrandis and Stevenson, 1985).

Enrichment and Isolation Procedures

Isolation of *Yersinia* strains from noncontaminated normally sterile samples (blood, lymph nodes) can be performed by using blood agar or nutrient agar incubated for 48 h at 28°C, or 24 h at 37°C followed by 24 h at room temperature. The isolation of *Y. pestis* from contaminated samples requires inoculation (subcutaneously or percutaneously) of animals (guinea pigs, mice, or rats). The organism can be recovered postmortem from the spleen, liver, or lymph nodes of the inoculated animals. All other *Yersinia* species can be isolated from clinical or food samples by inoculating standard or special selective media (reviewed by Bottone, 1992), of which cefsulodin-irgasan-novobiocin (CIN) agar (Schiemann, 1979), and virulent *Yersinia* enterocolitica (VYE) agar formulated by Fukushima (1987) seem the most useful. The latter medium was developed because of the growth inhibition of many *Y. bercovieri* and *Y. pseudotuberculosis* strains on CIN agar (Fukushima and Gomyoda, 1986). All these media should preferably be incubated for 48 h at 28–29°C or for 24 h at 37°C followed by 48–72 h at room temperature. Recovery of *Yersinia*

TABLE BXII.γ.284. Correlation of biogroup and serogroup with ecologic and geographic distribution

[a] *Y. enterocolitica* isolates comprising biogroup 1A may be opportunistic pathogens in patients with underlying disorders.

strains from contaminated samples can be improved by various cold enrichment techniques (van Pee and Straiger, 1979; Lee et al., 1980).

Maintenance Procedures

Stab inoculations of *Yersinia* strains in conventional stock culture media stored in the dark at room temperature or at 4°C provide living cultures for 10 years or more, if the tubes are tightly sealed. Lyophilization and deep-freeze storage in 10% glycerol are suitable preservation techniques. To keep a strain fully virulent, it should never be subcultured at 37°C, but always at 25–28°C.

Procedures for Testing Special Characters

Methods to test tetrathionate reduction, tellurite reduction, and the type of nitrate reductase have been described or referenced by Bercovier et al. (1979). The Ca^{2+}-dependency of virulent *Yersinia* strains is evaluated on magnesium oxalate medium[1] (Higuchi and Smith, 1961) as follows. Inoculate 0.1 ml of a bacterial suspension (10^5 cells/ml) onto two plates: one is incubated at 37°C, the other at 26°C. Check colony numbers on the two plates after 2–3 d. Colonies growing at 26°C but not at 37°C are Ca^{2+}-dependent. A fully virulent strain should give confluent growth at 26°C, whereas only 10–100 colonies should appear at 37°C. The autoagglutination test (Laird and Cavanaugh, 1980) to detect virulent *Yersinia* strains is performed by inoculating 10 or more isolated colonies, individually into a pair of tubes (13 × I00 mm) containing 2 ml of RPMI-1640 medium containing 10% fetal calf serum and 25 ml HEPES buffer (*N*-2-hydroxyethylpiperazine-*N*′-2-ethanesulfonic acid). One tube is incubated at 37°C, the other at 26°C. After incubation at 26°C for 18 h, virulent isolates give a uniform turbidity; at 37°C a layer of agglutinated bacteria appears at the bottom of the tube and the overlying supernatant remains clear. Avirulent strains give uniform turbidity at both 26°C and 37°C, and rough strains show spontaneous agglutination at both temperatures.

Differentiation of the genus *Yersinia* from other genera

Characteristics useful for differentiating *Yersinia* from other physiologically similar genera are listed in Table BXII.γ.280, and in Tables BXII.γ.193, BXII.γ.194, and BXII.γ.196 in the chapter on the family *Enterobacteriaceae*.

1. Magnesium oxalate medium consists of blood agar base (BBL, or any other manufacturer if the Ca^{2+} content of the base is low), 40.0 g; distilled water, 830 ml. Sterilize at 121°C for 15 min and cool to 45°C. From stock solution sterilized by filtration, aseptically add the following ingredients: $MgCl_2$ solution (23.8 g/l), 80 ml; sodium oxalate solution (33.5 g/l), 80 ml; and glucose solution (180.1 g/l), 10 ml.

Taxonomic Comments

The genus *Yersinia* was proposed by van Loghem (1944) in order to separate *Y. pestis* and *Y. pseudotuberculosis* (formerly in the genus *Pasteurella*) from *Pasteurella* species *sensu stricto* (i.e., *P. multocida*, etc.), from which they differ in their negative oxidase reaction and in their DNA base composition. The genus *Yersinia* belongs to the family *Enterobacteriaceae*. *E. coli* tDNA (i.e., the genes coding for transfer RNA) and *Y. pestis* tDNA are 63% related (Brenner et al., 1976), a value similar to that found for *E. coli* tDNA and *Hafnia alvei* tDNA. All *Yersinia* species express the common enterobacterial antigen. Their physiological characteristics and their fatty acid content are similar to those of all *Enterobacteriaceae* species. The mol% G + C range of *Yersinia* species is 46–50 and is consistent with that for *Enterobacteriaceae* species.

The genus *Yersinia* currently consists of 11 different species. Based on DNA–DNA hybridization studies, all of these species are more closely related to each other than to any other *Enterobacteriaceae* species (Brenner et al., 1980e; Bercovier et al., 1984; Aleksic et al., 1987; Wauters et al., 1988). The genus *Yersinia* can be considered a very homogeneous taxon.

DNA relatedness among *Yersinia* species is 40% or higher, except for *Y. ruckeri*, which is at most 38% related to other *Yersinia* species. DNAs of *Y. ruckeri* strains have been shown to be 30% related to *Serratia* species (Ewing et al., 1978). *Y. ruckeri* was included in *Yersinia* because its mol% G + C of 48 is closer to that of *Yersinia* species than to that of *Serratia* species. Because the phenotypic characteristics of *Y. ruckeri* are very different from those of other *Yersinia* species (Tables BXII.γ.281 and BXII.γ.282), it might constitute a new genus by itself. Phylogenetic studies would be helpful in clarifying this problem.

Strains of *Y. enterocolitica* belonging to the five different biovars (Table BXII.γ.283), including the metabolically inactive biovar 5 strains, constitute a homogeneous genomospecies (Bercovier et al., 1980a). The strains originally described as *Y. enterocolitica*-like organisms or atypical *Y. enterocolitica* have been separated into three different species: *Y. intermedia* (Brenner et al., 1980a), *Y. frederiksenii* (Ursing et al., 1980a), and *Y. kristensenii* (Bercovier et al., 1980c). *Y. frederiksenii* consists of three genetic groups based on DNA–DNA hybridization (Ursing et al., 1980a). For practical reasons, because there are no phenotypic differences among the three genetic groups, only one species, *Y. frederiksenii*, has been proposed for these rhamnose-positive strains. More study of phenotypic characteristics is needed to separate the three genetic groups.

The DNAs of *Y. pestis* strains, regardless of biovar, and of *Y. pseudotuberculosis* are 90% or more interrelated. This explains the antigenic and biochemical similarities of the two species. Based on DNA data, Bercovier et al. (1980b) proposed that the two

species constitute a single species, divided into two subspecies: *Y. pseudotuberculosis* subsp. *pseudotuberculosis* and *Y. pseudotuberculosis* subsp. *pestis*. Presently, however, the two species remain distinct, largely because of fear of omitting the subspecies epithet subsp. *pestis*, which may present a potential hazard for laboratory-acquired infections (Williams, 1983).

Ursing et al. (1980b) have shown, based on DNA and physiological data, that *Y. philomiragia* (Jensen et al., 1969) is not related to the genus *Yersinia*, and furthermore, that it is not a member of the family *Enterobacteriaceae*. This species has now been assigned to the genus *Francisella* as *F. philomiragia*.

Differentiation of the species of the genus *Yersinia*

Characteristics useful in differentiating the various species of *Yersinia* are listed in Table BXII.γ.282.

List of species of the genus Yersinia

1. **Yersinia pestis** (Lehmann and Neumann 1896) Van Loghem 1944, 15[AL] (*Bacterium pestis* Lehmann and Neumann 1896, 194; *Yersinia pseudotuberculosis* subsp. *pestis* Bercovier, Mollaret, Alonso, Brault, Fanning, Steigerwalt and Brenner 1981a, 383.)
pes′ tis. L. n. *pestis* plague, pestilence.

The characteristics are as described for the genus and as listed in Tables BXII.γ.281 and BXII.γ.282. Three biogroups have been described in relation to the geographical distribution of the organism: (a) biogroup antiqua produces acid aerobically from glycerol, reduces nitrate to nitrite, does not ferment melibiose, and is found in Central Asia and Central Africa; (b) biogroup medievalis produces acid from both glycerol and melibiose, but does not reduce nitrate to nitrite; it is found in Iran and the former USSR; and (c) biogroup orientalis (synonym: oceanic) does not produce acid from either glycerol or melibiose but reduces nitrate to nitrite and is distributed worldwide. Some rare atypical strains positive in their reactions for urease and L-rhamnose have been reported. *Y. pestis* is the causative agent of plague. The disease can be reproduced experimentally in mice, rats, guinea pigs, and monkeys.

The mol% G + C of the DNA is: 46 (T_m).
Type strain: ATCC 19428, NCTC 5923.

2. **Yersinia aldovae** Bercovier, Steigerwalt, Guiyoule, Huntley-Carter, and Brenner 1984, 171[VP]
al.do′ vae. M.L. gen. n. *aldovae* in honor of Eva Aldova, the Czechoslovakian microbiologist who first isolated the bacterium.

The characteristics are as described for the genus and as listed in Tables BXII.γ.281 and BXII.γ.282. The species is composed of isolates previously referred to as *Y. enterocolitica*-like, group X2 (Bercovier et al., 1980a). Two biovars exist—one typically sucrose negative, and one sucrose positive. Differentiation of *Y. aldovae* from urease-positive *Hafnia alvei* may be achieved by production of gas by *H. alvei* from D-glucose at 36°C and susceptibility to *Hafnia* specific bacteriophage (Guinée and Valkenburg, 1968). *Y. aldovae* has been isolated from aquatic ecosystems—drinking water, river water, fish, and rarely soil. *Y. aldovae* has not been implicated in animal infections and has not been isolated from humans.

The mol% G + C of the DNA is: 48 (T_m).
Type strain: ATCC 35236, CNY 6065.
GenBank accession number (16S rRNA): X75277.

3. **Yersinia bercovieri** Wauters, Janssens, Steigerwalt, and Brenner 1988, 428[VP]
ber.co.vi.e′ ri. M.L. n. *bercovieri* in honor of Herve Bercovier, who first described biogroups 3A and 3B and has made outstanding contributions to the taxonomy and ecology of yersiniae.

Formerly called *Y. enterocolitica* biogroup 3b (Bercovier et al., 1978). Later transferred to *Y. enterocolitica* biogroup 6 (Wauters et al., 1987) because of negative Voges–Proskauer reaction. *Y. bercovieri* must be distinguished from rarely occurring pathogenic strains of serogroup 0:3 that are Voges–Proskauer-negative variants of biogroup 3 (Kaneko and Maruyama, 1987). The species conforms to the definition of the family *Enterobacteriaceae* and the genus *Yersinia*. The characteristics are as described for the genus and as listed in Tables BXII.γ.281 and BXII.γ.282. *Y. bercovieri* strains have been isolated from human stool specimens, animals, raw vegetables, soil, and water. There is no evidence of pathogenicity for humans.

The mol% G + C of the DNA is: 50 (T_m).
Type strain: ATCC 43970, CDC 2475-87.

4. **Yersinia enterocolitica** (Schleifstein and Coleman 1943)

Frederiksen 1964, 104[AL] (*Bacterium enterocoliticum* Schleifstein and Coleman 1943, 56.)
en.ter.o.co.li′ ti.ca. Gr. n. *enteron* intestine; Gr. n. *colon* of the colon; Gr. suff. *iticos* pertaining to; M.L. fem. adj. *enterocolitica* pertaining to the intestine and colon.

The characteristics are as described for the genus and listed in Tables BXII.γ.281 and BXII.γ.282. The Voges–Proskauer test is usually positive at 22–28°C and negative at 37°C. Biovars of *Yersinia enterocolitica* are listed in Table BXII.γ.283 and, like phagovars and serogroups, are useful epidemiological tools. Rare atypical strains that are either positive for their reactions on Simmons' citrate and for acid production from lactose and raffinose (due to a metabolic plasmid) or negative for urease activity have been reported. When incubated at 20°C, *Y. enterocolitica* strains produce a broad-spectrum mannose-resistant hemagglutinin that is lost at 37°C (MacLagan and Old, 1980). *Y. enterocolitica* causes diarrhea, terminal ileitis, mesenteric lymphadenitis, autoimmune arthritis, abscesses, and septicemia in humans. The disease can be reproduced experimentally in mice, gerbils, and monkeys. Other human infections are listed in Table BXII.γ.285. The species has been isolated from a wide variety of sources in the environment (live and inanimate) including foods and from healthy humans and animals, especially the pig.

The mol% G + C of the DNA is: 48.5 ± 1.5 (T_m, Bd).
Type strain: 161, ATCC 9610, CIP 80-27, DSM 4780.
GenBank accession number (16S rRNA): M59292.
Additional Remarks: The type strain belongs to biovar I B, serogroup 0:8, and phagovar X.

5. **Yersinia frederiksenii** Ursing, Brenner, Bercovier, Fanning, Steigerwalt, Brault and Mollaret 1981, 217[VP] (Effective publication: Ursing, Brenner, Bercovier, Fanning, Steigerwalt, Brault and Mollaret 1980a, 213.)
fred.er.ik.sen′ i.i. M.L. gen. n. *frederiksenii* of Frederiksen; named after the Danish microbiologist Wilhelm Frederiksen, who made a substantial contribution to the study of the genus *Yersinia*.

The characteristics are as described for the genus and as listed in Tables BXII.γ.281 and BXII.γ.282. This species is composed of three different genomospecies. One group is positive for β-xylosidase and citrate (Simmons), and the type strain belongs to this group. The other two groups are variable or negative for these tests. More phenotypic studies are needed to differentiate the three groups. Some strains are able to ferment raffinose and lactose when they harbor a metabolic plasmid. *Y. frederiksenii* has been isolated mainly from fresh water sources, fish, foods, and occasionally from healthy or sick humans and animals.

The mol% G + C of the DNA is: 48 (T_m).
Type strain: 6175, CIP 80-29.

TABLE BXII.γ.285. Spectrum of *Yersinia enterocolitica* infections

Type of infection	Manifestation/population
Gastrointestinal	Enterocolitis, predominantly in young children; concomitant bacteremia may also be present in infants
	Pseudoappendicitis syndrome (children older than 5 years; adults), acute mesenteric lymphadenitis; terminal ileitis
Septicemia	Especially in immunosuppressed individuals and those in iron overload or being treated with deferrioxamine; transfusion related (usually leads to septic shock syndrome)
Metastatic	Focal abscesses: liver, kidney, spleen, lung; cutaneous manifestations: cellulitis, pyomyositis, pustules, and bullous lesions; pneumonia, cavitary pneumonia; meningitis; panophthalmitis; endocarditis, infected mycotic aneurysm; osteomyelitis
Postinfection sequelae	Arthritis (associated with HLA-B-27), myocarditis, glomerulonephritis, erythema nodosum

6. **Yersinia intermedia** Brenner, Bercovier, Ursing, Alonso, Steigerwalt, Fanning, Carter and Mollaret 1981, 217[VP] (Effective publication: Brenner, Bercovier, Ursing, Alonso, Steigerwalt, Fanning, Carter and Mollaret 1980a, 207.)
in.ter.me′ di.a. L. fem. adj. *intermedia* intermediate; here it implies that biochemical reactions of this species seem midway between *Y. enterocolitica* and *Y. pseudotuberculosis*.

The characteristics are as described for the genus and as listed in Tables BXII.γ.281 and BXII.γ.282. Media with a high bile salt content (0.8%) are inhibitory, especially when incubated at 37°C. Some biochemical characteristics (citrate utilization; cellobiose, L-rhamnose, and raffinose fermentation) are always expressed at 25–28°C but are inconstant at 37°C. Either a type A or a type B nitrate reductase is present. Eight biovars have been described (Brenner et al., 1980a) based on the fermentation of melibiose, L-rhamnose, α-methyl-D-glucoside, and raffinose, and on the utilization of citrate (Simmons). Of the strains studied, 96% are positive for at least four of these five tests. *Y. intermedia* has been isolated mainly from fresh water sources, fish, foods, and occasionally from both sick and healthy humans (Bottone et al., 1974; Punsalang et al., 1987).

The mol% G + C of the DNA is: 48.5 ± 0.5 (T_m, Bd).
Type strain: 3953, Bottone 48, Chester 48, ATCC 29909, CIP 80-28.

7. **Yersinia kristensenii** Bercovier, Ursing, Brenner, Steigerwalt, Fanning, Carter and Mollaret 1981b, 217[VP] (Effective publication: Bercovier, Ursing, Brenner, Steigerwalt, Fanning, Carter and Mollaret 1980c, 219.)
kris.ten.se′ ni.i. M.L. gen. n. *kristensenii* of Kristensen, named after the Danish microbiologist Martin Kristensen, who first isolated this organism.

The characteristics are as described for the genus and as listed in Tables BXII.γ.281 and BXII.γ.282. Growth is delayed (7 d) when cultures are incubated at 41°C and even at 37°C for some isolates. Some strains utilize citrate (Simmons) after 7-d incubation at 25°C. Most strains produce a "musty" or "cabbage-like" odor when grown on nutrient agar. Some strains produce an enterotoxin (ST) when incubated at 22°C and also at 37°C (Kapperud, 1980). *Y. kristensenii* strains have been isolated mainly from environmental sources such as soil, fresh water, foods, and rarely from healthy human and animal carriers. *Y. kristensenii* may occasionally be associated with human enteritis (Bottone and Robin, 1977), and *Y. kristensenii* isolates may be lethal to mice pretreated with iron dextrin (Robins-Browne et al., 1991).

The mol% G + C of the DNA is: 48.5 ± 0.5 (T_m, Bd).
Type strain: 105, ATCC 33638, CIP 80-30.

8. **Yersinia mollaretii** Wauters, Janssens, Steigerwalt, and Brenner 1988, 427[VP]
mol.la.re' ti.i. M.L. gen. n. *mollaretii* in honor of Henri H. Mollaret, head of the National *Yersinia* Center at the Pasteur Institute in Paris, for his years of study on the classification and epidemiology in the genus *Yersinia*.

Formerly called *Y. enterocolitica* biogroup 3A (Bercovier et al., 1978). Later transferred to *Y. enterocolitica* biogroup 6 (Wauters et al., 1987) because of negative Voges-Proskauer reaction (typical serotype 0:3 strains are Voges–Proskauer positive). *Y. mollaretii* must be distinguished from rarely occurring pathogenic strains of serogroup 0:3 that are Voges–Proskauer-negative variants of biogroup 3 (Kaneko and Maruyama, 1987). The characteristics are as described for the genus and as listed in Tables BXII.γ.281 and BXII.γ.282. The species conforms to the definition of the family *Enterobacteriaceae* and the genus *Yersinia*. *Y. mollaretii* strains have been isolated from human stool specimens, meat, raw vegetables, soil, and drinking water, and lack virulence markers. There is no evidence of pathogenicity for humans.

The mol% G + C of the DNA is: 50–51 (T_m).

Type strain: ATCC 43969, CDC 2465-87.

9. **Yersinia pseudotuberculosis** (Pfeiffer 1889) Smith and Thal 1965, 220[AL] (*Bacillus pseudotuberculosis* Pfeiffer 1889, 5; *Yersinia pseudotuberculosis* subsp. *pseudotuberculosis* (Pfeiffer 1889) Smith and Thal 1965, 220.)
pseu.do.tu.ber.cu.lo' sis. Gr. adj. *pseudes* false; M.L. fem. n. *tuberculosis* tuberculosis; M.L. gen. n. *pseudotuberculosis* of false tuberculosis.

The characteristics are as described for the genus and as listed in Tables BXII.γ.281 and BXII.γ.282. Some freshly isolated strains may require subculturing before expressing their motility. Strains belonging to serogroup IV are citrate positive (Simmons) and malonate positive. Up to 5% of *Y. pseudotuberculosis* strains have been reported to produce acid from adonitol. Some strains, mostly of serogroup III, produce an exotoxin that differs from the *Y. pestis* toxin. Its biological activity is not well defined. *Y. pseudotuberculosis* is a human and animal pathogen responsible for mesenteric lymphadenitis, diarrhea, and septicemia. The disease can be reproduced experimentally in guinea pigs challenged per os and in mice.

The mol% G + C of the DNA is: 46.5 (T_m).

Type strain: ATCC 29833, DSM 8992, NCTC 10275.

Additional Remarks: The type strain belongs to serogroup I.

10. **Yersinia rohdei** Aleksic, Steigerwalt. Bockemühl, Huntley-Carter, and Brenner 1987, 330[VP]
roh' de.i. M.L. gen. n. *rohdei* of Rohde; named in honor of the late Rolf Rohde, who founded the National Reference Center for *Salmonella* in Hamburg, Federal Republic of Germany, and who made many significant contributions to the diagnostic and serological identification of *Enterobacteriaceae*, especially *Salmonella*.

The characteristics are as described for the genus and listed in Tables BXII.γ.281 and BXII.γ.282. Two biovars are recognized based on positive (biovar 1) or negative (biovar 2) reactions for both raffinose and melibiose. *Y. rohdei* strains were isolated from the feces of dogs and humans and from surface water. The clinical significance of *Y. rohdei* as a diarrheal agent in humans and animals is uncertain.

The mol% G + C of the DNA is: 49.1 (T_m).

Type strain: H271-36/78, ATCC 43380.

Additional Remarks: The type strain was isolated from dog feces in Germany in 1978.

11. **Yersinia ruckeri** Ewing, Ross, Brenner and Fanning 1978, 37[AL]
ru' cker.i. M.L. gen. n. *ruckeri* of Rucker; named after R.R. Rucker, who studied the red mouth disease and its etiological agents.

The characteristics are as described for the genus and as listed in Tables BXII.γ.281 and BXII.γ.282. The cells are 1×2–3 µm. Filaments can be seen in old cultures (48 h at 22°C). Colonies on nutrient agar are smooth, circular, and slightly raised. Growth is delayed or inhibited on Salmonella–Shigella agar incubated at 37°C but not at 22°C. Corn oil is hydrolyzed when the test is performed at 22°C but not at 37°C. *Y. ruckeri* is one of the agents responsible for red mouth disease in rainbow trout. The disease can be transmitted experimentally from fish to fish. The organism was initially isolated only in North America, but reports of enteric red mouth disease caused by *Y. ruckeri* have also assumed increasing importance in fish farms in Europe (Home et al., 1984). First isolated in 1959 from a dead muskrat found in a marshy area at the Bear River Migratory Bird Refuge in northern Utah. Other strains have been isolated from water in the same area.

The mol% G + C of the DNA is: 48 ± 0.5 (Bd).

Type strain: ATCC 29473.

GenBank accession number (16S rRNA): X75275.

Genus XLII. **Yokenella** *Kosako, Sakazaki, and Yoshizaki 1985, 224[VP] (Effective publication: Kosako, Sakazaki, and Yoshizaki 1984, 124)*

J.J. Farmer III and Frances W. Brenner

Yoken.el' la. dim. ending *-ella;* Japanese abbreviation *"Yoken"* that stands for the National Institute of Health, Tokyo, Japan; M.L. fem. n. *Yokenella* pertaining to Yoken, the National Institute of Health, Tokyo, Japan where the new group of organisms was recognized and studied.

Rod-shaped cells, conforming to the general definition of the family *Enterobacteriaceae*. Contain the enterobacterial common antigen. Gram negative. Motile, with peritrichous flagella. Facultatively anaerobic. Catalase positive (weak). Oxidase negative. Ferment, rather than oxidize, D-glucose and other carbohydrates. Reduce nitrate to nitrite.

Positive for methyl red, citrate utilization (Simmons), lysine decarboxylase, ornithine decarboxylase, motility at 36°C, and

growth in the presence of cyanide (KCN test), β-galactosidase (ONPG test), tetrathionate reductase, and the fermentation of D-mannitol, L-arabinose, L-rhamnose, maltose, D-xylose, trehalose, cellobiose, melibiose, D-mannose, D-galactose, L-fucose, and D-gluconate. Produce visible gas during fermentation.

Negative for indole production, Voges–Proskauer, H_2S production (TSI), urea hydrolysis, phenylalanine deaminase, arginine dihydrolase, malonate utilization, gelatin hydrolysis (22°C), lipase (corn oil and Tween 80), DNase, esculin hydrolysis, pectinase, chitinase, β-xylosidase, growth at 4°C, and the fermentation of lactose, sucrose, dulcitol, salicin, adonitol, *myo*-inositol, D-sorbitol, raffinose, α-methyl-D-glucoside, erythritol, D-arabitol, glycerol, and mucate.

Susceptible to nalidixic acid, sulfadiazine, gentamicin, kanamycin, tetracycline, and chloramphenicol (disk diffusion method on Mueller-Hinton agar); **usually resistant to colistin, penicillin, ampicillin, carbenicillin, and cephalothin**; variable susceptibility to streptomycin.

Ecological niches are not known, but has been **isolated from human clinical specimens**, insects, and water. **Probably an opportunistic pathogen** for humans. A **rarely isolated member of the *Enterobacteriaceae*.**

The mol% G + C of the DNA is: 58–59.3 (T_m).

Type species: **Yokenella regensburgei** Kosako, Sakazaki, and Yoshizaki 1985, 224 (Effective publication: Kosako, Sakazaki, and Yoshizaki 1984, 124.)

Further descriptive information

Different names for the same organism It is essential for the reader to understand that three vernacular names (*"Hafnia"* species 3, Enteric Group 45, and NIH biogroup 9) and one scientific name (*Koserella trabulsii*) have been used in the literature for the organism that is known today as *Yokenella regensburgei*. This is explained in the section Taxonomic Comments. Until recently, the names *Koserella* and *K. trabulsii* appeared in the literature, so we have inserted these names in parentheses if they were used in the original article.

Literature Since *Yokenella* and *Koserella* were described in 1984–85, there have been several reports in the literature. In addition to the two genus and two species names, "*Hafnia* species 3", "Enteric Group 45", and "NIH biogroup 9" should also be included in computerized literature searches, although these names are rarely used today.

Sources, strains, collections Strains of *Y. regensburgei* have been isolated from a variety of human clinical specimens and other sources. The original isolates of Kosako et al. (1984) were from human clinical specimens; urine (three isolates), wound (one), and abscess (one), and six isolates from insect intestine. The original collection of Hickman-Brenner et al. (1985a) included the type strain for *K. trabulsii* isolated from a wrist wound of a 28-year-old man. The other isolates were from human wounds (four), sputum (two), throat (one), stool (one), knee fluid (one), well water (one), and unknown (one). Since that original report, the CDC has received 10 additional human strains (three wound, two blood, two sputum, one urine, one lung biopsy, and one unknown). The first blood isolate was from a 35-year-old woman who had a bone marrow transplant. Group G streptococci and *Klebsiella pneumoniae* were also isolated. No further clinical information was given for the remaining strains.

Isolates from other sources Six of the original strains reported by Kosako et al. (1984) were originally isolated by F. Haas (Germany) from the intestine of *Heteroptera* (*Pyrrhcoris apterus*). Cassel-Beraud and Richard (1988) studied stools of 88 insect eating bats (*Chaerephon pumila*), which yielded many different bacterial strains. Strains of *K. trabulsii* were identified among the 20 different species identified, most of which were *Enterobacteriaceae*.

Clinical significance Whether *Yokenella* strains can actually cause infections is still being evaluated. Systematic study and additional case reports are needed. Abbott and Janda (1994a) reported two cases that yielded *Y. regensburgei*; one was a 74-year-old man with a "septic knee", and the other was a 35-year-old immunocompromised woman without overt signs of sepsis but with a positive blood culture. Yague et al. (1989) described two cases (*K. trabulsii*) from Spain. The first case involved an isolate from the stool of a 4-year-old boy. *Campylobacter jejuni* was also isolated and was considered to be the causative agent. The second case involved an isolate from the urine of an 88-year-old man with fever and respiratory problems. The colony count was over 100,000 CFU/ml, but there was no evidence of a urinary tract infection. *K. trabulsii* was not considered significant in either case.

Other literature The literature includes reviews and taxonomic studies of new *Enterobacteriaceae* (Richard, 1989; Gilchrist, 1995; Pokhil, 1996; Aleksic and Bockemühl, 1999), and surveys or comparisons of the family *Enterobacteriaceae* for acid phosphatases (Thaller et al., 1995) and polyamines (Hamana, 1996).

Isolation, identification, culture preservation, phenotypic characterization Strain of *Y. regensburgei* are not difficult to grow, and are typical *Enterobacteriaceae* in most respects. See the chapter on the family *Enterobacteriaceae* for general information on growth, plating media, working and frozen stock cultures, media and methods for biochemical testing, identification, computer programs, and antibiotic susceptibility.

Biochemical reactions and differentiation from other *Enterobacteriaceae* Table BXII.γ.193 in the chapter on the family *Enterobacteriaceae* gives the results for *Y. regensburgei* in 47 biochemical tests normally used for identification (Farmer, 1999). There are no genus- or species-specific tests or sequences for the identification. The best approach is to do a complete set of phenotypic tests (growth on plating media, biochemical tests, antibiogram, etc.) and compare the results with all the other named organisms in the family *Enterobacteriaceae*. This approach is described in more detail in the chapter on the family *Enterobacteriaceae*. The biochemical results of a test strain can be compared to all the organisms listed in Table BXII.γ.193 in that section. Several computer programs greatly facilitate analyzing the results. Biochemically, *Yokenella regensburgei* is closest to *Hafnia alvei*. These two organisms can be differentiated because *Y. regensburgei* is Voges–Proskauer and glycerol negative; citrate (Simmons), cellobiose, and melibiose positive; and resistant to colistin and to the *Hafnia*-specific bacteriophage of Guinée and Valkenburg (1968). It also gives a weak, delayed, catalase reaction. These are in contrast to the reactions of *Hafnia alvei*.

Taxonomic Comments

Today there is general agreement on the use of the names *Yokenella* and *Yokenella regensburgei*. However, the names *Koserella* and *Koserella trabulsii* also appear in the literature. Table BXII.γ.192 in the chapter on the family *Enterobacteriaceae* summarizes how these organisms were discovered, named, and how *Yokenella regensburgei* eventually displaced *Koserella trabulsii*.

Agreement to use *Yokenella* rather than *Koserella* Although the CDC workers did not agree with the manner in which Kosako and Sakazaki (1991) proceeded in trying to solve the nomenclatural problem of priority, they decided to use *Yokenella* and *Y. regensburgei* instead of *Koserella* and *K. trabulsii*. In McWhorter et al. (1991), one of us (JJF) wrote: "We now acknowledge that *Y. regensburgei* has priority over *K. trabulsii* because *Y. regensburgei* was published first and gained standing in nomenclature in the same issue of the *International Journal of Systematic Bacteriology* as *K. trabulsii*. In a nomenclatural sense, *K. trabulsii* should now be considered a 'junior subjective synonym' of *Y. regensburgei* and thus an illegitimate name. We will now use the name *Y. regensburgei* instead of the name *K. trabulsii*."

McWhorter et al., 1991 conceded that only quirks in the validation process had given priority to *Koserella* over *Yokenella*, and agreed that since the names *Yokenella* and *Yokenella regensburgei* were published first and should have appeared first in a validation list, they should be used. Publications, databases, computer programs, and biochemical charts of CDC have reflected this use of *Yokenella* rather than *Koserella*. For example, compare Table 1 of Farmer (1999) that used *K. trabulsii* with Table 1 of Farmer (1995) that used *Y. regensburgei*. This informal acceptance resolved the issue as far as usage; however, only an Opinion of the Judicial Commission in the future can resolve the nomenclatural problem described below.

Nomenclatural problem — do *Yokenella* and *Y. regensburgei* have priority over *Koserella* and *K. trabulsii*? Under the rules of the Bacteriological Code, the answer to this question is unclear. Kosako and Sakazaki (1991) argued clearly and logically for their priority, but this was clearly an opinion of Kosako and Sakazaki, which has no judicial standing under the Bacteriological Code. Unfortunately, they did not end the title of their paper with "Request for an Opinion" as previously agreed to resolve the problem of priority (Kosako et al., 1987). The rules of the Bacteriological Code are interpreted differently by different people, and their application in unique circumstances is also a matter of interpretation. Thus, the question of priority remains as only a small nomenclatural problem because the matter of usage was settled in the early 1990s.

List of species of the genus Yokenella

1. **Yokenella regensburgei** Kosako, Sakazaki, and Yoshizaki 1985, 224[VP] (Effective publication: Kosako, Sakazaki, and Yoshizaki 1984, 124.)
re.gens.bur′ ge.i. M.L. gen. *regensburgei* pertaining to Regensburg, Germany, where the type strain of *Y. regensburgei* and five other strains in the original paper (Kosako et al., 1984) were isolated from insects.

The characteristics are as given for the genus. Isolated from human clinical specimens (blood, urine, feces, throat and sputum, wounds, abscess, and others), insect intestines, and well water. Its clinical significance is not known, but if it is pathogenic for humans it is probably a very weak pathogen. However, it is also possible that it is colonizing rather than infecting body sites that are normally not sterile. There is no evidence that it can cause diarrhea or intestinal infections. It should be considered a rarely isolated species of *Enterobacteriaceae* that is probably an opportunistic pathogen for humans. The type strains was isolated by F. Haas from the intestine of an insect (*Pyrrhocoris apterus*) in Regensburg, Germany.

The mol% G + C of the DNA is: 58–59.3 (T_m).

Type strain: ATCC 49455, CDC 3020-86, NIH 725-83, JCM 2403.

Additional Remarks: The American Type Culture Collection includes the five strains of *Y. regensburgei* that were originally deposited by Hickman-Brenner et al. (1985a) as *Koserella trabulsii*. Four were from human clinical specimens and one was from well water.

Order XIV. **Pasteurellales** *ord. nov.*

George M. Garrity, Julia A. Bell and Timothy Lilburn

Pas.teu.rel.la′ les. M.L. fem. n. *Pasteurella* type genus of the order; *-ales* suffix to denote order; M.L. fem. n. *Pasteurellales* the *Pasteurella* order.

The order *Pasteurellales* was circumscribed for this volume on the basis of phylogenetic analysis of 16S rDNA sequences; the order contains the family *Pasteurellaceae*.

Description is the same as for the family *Pasteurellaceae*.

Type genus: **Pasteurella** Trevisan 1887, 94 (Nom. Cons. Opin. 13, Jud. Comm. 1954b, 153.)

Agreement to use *Yokenella* rather than *Koserella* Although the CDC workers did not agree with the manner in which Kosako and Sakazaki (1991) proceeded in trying to solve the nomenclatural problem of priority, they decided to use *Yokenella* and *Y. regensburgei* instead of *Koserella* and *K. trabulsii*. In McWhorter et al. (1991), one of us (JJF) wrote: "We now acknowledge that *Y. regensburgei* has priority over *K. trabulsii* because *Y. regensburgei* was published first and gained standing in nomenclature in the same issue of the *International Journal of Systematic Bacteriology* as *K. trabulsii*. In a nomenclatural sense, *K. trabulsii* should now be considered a 'junior subjective synonym' of *Y. regensburgei* and thus an illegitimate name. We will now use the name *Y. regensburgei* instead of the name *K. trabulsii*."

McWhorter et al., 1991 conceded that only quirks in the validation process had given priority to *Koserella* over *Yokenella*, and agreed that since the names *Yokenella* and *Yokenella regensburgei* were published first and should have appeared first in a validation list, they should be used. Publications, databases, computer programs, and biochemical charts of CDC have reflected this use of *Yokenella* rather than *Koserella*. For example, compare Table 1 of Farmer (1999) that used *K. trabulsii* with Table 1 of Farmer (1995) that used *Y. regensburgei*. This informal acceptance resolved the issue as far as usage; however, only an Opinion of the Judicial Commission in the future can resolve the nomenclatural problem described below.

Nomenclatural problem — do *Yokenella* and *Y. regensburgei* have priority over *Koserella* and *K. trabulsii*? Under the rules of the Bacteriological Code, the answer to this question is unclear. Kosako and Sakazaki (1991) argued clearly and logically for their priority, but this was clearly an opinion of Kosako and Sakazaki, which has no judicial standing under the Bacteriological Code. Unfortunately, they did not end the title of their paper with "Request for an Opinion" as previously agreed to resolve the problem of priority (Kosako et al., 1987). Order XIV. **Pasteurellales** *ord. nov.*

George M. Garrity, Julia A. Bell and Timothy Lilburn

Pas.teu.rel.la' les. M.L. fem. n. *Pasteurella* type genus of the order; *-ales* suffix to denote order; M.L. fem. n. *Pasteurellales* the *Pasteurella* order.

The order *Pasteurellales* was circumscribed for this volume on the basis of phylogenetic analysis of 16S rDNA sequences; the order contains the family *Pasteurellaceae*.

Description is the same as for the family *Pasteurellaceae*.

Type genus: **Pasteurella** Trevisan 1887, 94 (Nom. Cons. Opin. 13, Jud. Comm. 1954b, 153.)

Family I. **Pasteurellaceae** Pohl 1981b, 382^VP (Effective publication: Pohl 1979, 81)

Ingar Olsen, Floyd E. Dewhirst, Bruce J. Paster and Hans-Jürgen Busse

Pas.teu.rel.la′ ce.ae. M.L. fem. n. *Pasteurella* type genus of the family; *-aceae* suffix to denote a family; M.L. fem. pl. n. *Pasteurellaceae* the *Pasteurella* family.

Cells are straight, rigid, **coccoid to rod-shaped**, usually **0.2–0.4 × 0.4–2.0 μm**, nonsporeforming, **Gram negative**, and **nonmotile**. Pleomorphism with cell swelling and formation of filaments can be seen. Demethylmenaquinones, menaquinones, and ubiquinones may or may not be produced. Organisms are **aerobic, with varying degrees of microaerophilia, or facultatively anaerobic**. Both **respiratory and fermentative forms of metabolism** can be found among these organisms, which are **chemoorganotrophic**. Optimal growth temperature is 37°C. Acid is produced through fermentation of D-glucose, other carbohydrates, sugar alcohols, or glycosides. Conventional fermentation test media may not detect accumulation of acid fermentation products from some of the most fastidious species. Usually anaerogenic, but gas-producing species do occur. Fumarate is usually used as a terminal electron acceptor in demethylmenaquinone-mediated anaerobic respiration. Characteristically, **oxidase, catalase, and alkaline phosphatase reactions are positive**, but negative reactions can be detected in some species. **Nitrates are reduced to nitrites.** For primary isolation, complex media supplemented with yeast extract, serum, or whole blood lysate are required. Furthermore, organic nitrogen sources, amino acids, B vitamins, nicotinamide adenine nucleotides, hematin, or protoporphyrin may be needed. Members of the family are **obligate parasites in vertebrates (primarily mammals and birds)**. They inhabit mucous membranes of the alimentary, genital, or respiratory tracts and are often pathogenic in humans, other mammals, birds, and reptiles. Species are generally susceptible to benzylpenicillin and other β-lactam antibiotics, inhibitors of 70S ribosomal protein biosynthesis, as well as sulfonamides, trimethoprim, erythromycin, and colistin. The genome size is $1.2–2.2 \times 10^9$ Da.

The mol% G + C of the DNA is: 37–45.

Type genus: **Pasteurella** Trevisan 1887, 94 (Nom. Cons. Opin. 13, Jud. Comm. 1954b, 153.)

Circumscription, position and rank Sneath and Johnson (1973), who made numerical phenetic analyses on a restricted number of species, were probably the first authors to indicate that the genera *Actinobacillus*, *Haemophilus*, and *Pasteurella* could form a family. Mannheim et al. (1980) suggested from genetic studies that the genera *Actinobacillus*, *Haemophilus*, and *Pasteurella* should rank as a family, although some species were misclassified and should be removed. In 1979, Pohl proposed the name *Pasteurellaceae* for the family and the maintenance of the three genera as distinct entities (Pohl, 1979). From the results of DNA reassociation experiments, Pohl (1981a) suggested that some rearrangement of the species in the various genera was indicated. Single-linkage clustering of the DNA hybridization data revealed complex intra- and intergeneric relations at or above the 30% DNA–DNA reassociation level. Furthermore, phylogenetic studies based on 16S rDNA sequencing concluded that taxonomic division of the family into phylogenetically and phenotypically coherent genera was problematic (Dewhirst et al., 1992, 1993, 1995; Paster et al., 1995). Nevertheless, such studies contributed to clarification of the taxonomic position of several taxa within the *Pasteurellaceae* (Holmes, 1998).

The genus *Lonepinella* was effectively published (Osawa et al., 1995b) and validated (Osawa et al., 1996) as a fourth genus of the family. This genus was described to encompass isolates from the feces of koala that degrade a tannin–protein complex. So far, the genus consists of only one species, *Lonepinella koalarum*. 16S rDNA sequence analyses have clearly demonstrated that the genus *Lonepinella* clusters within the family *Pasteurellaceae*.

The genus *Mannheimia*, previously the *P. haemolytica* complex, has been validly published as a fifth genus (Angen et al., 1999a). Seven species were identified, five of which were formally named.

The genus *Phocoenobacter* has been validly published as a sixth genus in the family *Pasteurellaceae* and contains the single species *Phocoenobacter uteri* (Foster et al., 2000).

rRNA–DNA hybridization studies showed that the family *Pasteurellaceae* forms one cluster that is linked with both branches of the genus *Alteromonas*, the family *Enterobacteriaceae*, the family *Vibrionaceae*, and the family *Aeromonadaceae* (De Ley et al., 1990). All these clusters constitute superfamily I *sensu* De Ley which together with superfamily II corresponds to the *Gammaproteobacteria*.

16S rDNA sequencing of 54 strains (Dewhirst et al., 1992) and subsequently of 70 strains (Dewhirst et al., 1993) confirmed that the family *Pasteurellaceae* is located in the *Gammaproteobacteria* and demonstrated that the family *Pasteurellaceae* forms a compact phylogenetic group that is distinct from neighboring families. The sequence signatures reported previously for the family (Dewhirst et al., 1992) are still useful, particularly 667 A, 739 U, 831 G, and 855 C. However, if a full sequence is available, it is much better to place the sequence in a phylogenetic tree with appropriate outgroups than to examine only a few signature bases. The DNA probe 5′-ACCAACTACCTAATCCCACTTGGG-3′ hybridizes with DNA (at ~80%) from most of the members of the family, but not with members of other taxa, so the specificity is 100% (Dewhirst et al., 1992).

The phenotypic traits that distinguish the *Pasteurellaceae* from other families and genera are presented in Table BXII.γ.286. The dearth of clearly distinguishing phenotypic traits is a reason that phylogenetic placement at the genus and higher level must rely heavily on molecular sequence data. Nonmotile and nutritionally fastidious strains of *Enterobacteriaceae*, *Bacillus*, or aerotolerant clostridia, as well as nonfermentative organisms, can be mistaken for species of *Pasteurellaceae* (Mannheim, 1984).

The cellular fatty acid content of *Pasteurellaceae* is uniform, with only minor variations. Separation from the *Neisseriaceae* and from *Moraxella* is possible (Mutters et al., 1993). In addition, the distribution of phospholipids is uniform within *Pasteurellaceae*. Cellular carbohydrates show a common pattern within all members of the family, but characteristic profiles discriminate between groups, often to the species level (Mutters et al., 1993).

Respiratory quinones had been previously considered useful in defining the family. When selected members of the family *Pasteurellaceae* were investigated for their lipoquinone contents using high-performance liquid chromatography (Kroppenstedt and Mannheim, 1989), menaquinones (MK-7 or MK-8 or both), demethylmenaquinones (DMK-7 or DMK-8 or both) and ubi-

quinones (Q-7 or Q-8 or both) were detected in varying proportions. Similar results were obtained in another study concerning strains of *Pasteurella* that were grown under strictly aerobic conditions (Kainz et al., 2000). The view that *Pasteurellaceae* can be distinguished from the *Enterobacteriaceae* and other fermenting Gram-negative bacteria by lack of menaquinones can therefore not be supported. Although the situation is more complex than had previously been recognized, the distribution patterns of lipoquinone structural types and their isoprenologue analogs remain a reliable chemotaxonomic tool for these bacteria.

Genera and Taxonomic Problems There are six genera in the family *Pasteurellaceae*: *Pasteurella*, *Actinobacillus*, *Haemophilus*, *Lonepinella*, *Mannheimia* and *Phocoenobacter*. Phenotypic traits that are useful for distinguishing the genera are listed in Table BXII.γ.287. As can be seen by the distressingly large number of traits that are variable, there is little phenotypic consistency within genera, even when the genera are restricted to monophyletic groups based on DNA–DNA hybridization or 16S rDNA sequence analysis. The phylogeny and taxonomy of the family are clearly problematic. Several approaches to elucidating taxonomy have been used, including numerical taxonomy (Sneath and Johnson, 1973; Olsen, 1993), DNA–DNA hybridization (Mannheim and Pohl, 1980; Mannheim et al., 1980; Mannheim, 1983; Escande et al., 1984), rRNA–DNA hybridization (De Ley et al., 1990), genetic transformation (Albritton et al., 1986), chemotaxonomy (Olsen, 1993), and content of cellular fatty acids (Mutters et al., 1993), quinones (Mannheim, 1981; Kroppenstedt and Mannheim, 1989); Engelhard et al., 1991, 1992; Mutters et al., 1993; Kainz et al., 2000), polyamines (Busse et al., 1997), and cellular carbohydrates (Mutters et al., 1993). While these methods have clearly advanced our understanding of the taxonomy of the *Pasteurellaceae* (Bisgaard, 1995), it is now recognized that 16S sequencing is the most useful method for determining phylogeny and unraveling taxonomy at the genus and higher levels

[h]Some strains of *H. influenzae* are positive.

[i]*A. suis* is negative.

(Olsen and Woese, 1993), while DNA–DNA hybridization is the most useful at the species level.

Organisms of the family *Pasteurellaceae* infect most vertebrate species. In almost every vertebrate species examined carefully, multiple, often unique, *Pasteurellaceae* species have been recovered. Only a subset of these taxa has been formally named, but a large number of strains have found their way into culture collections, and many have been characterized and placed in tentative taxonomic groups. With the advent of 16S rDNA sequence analysis, it has been possible to rapidly examine strains representing these taxa and place them in an overall *Pasteurellaceae* phylogenetic tree. 16S rRNA-based phylogenies have previously been presented by a number of investigators (Dewhirst et al., 1992, 1993) but substantial new data exist, which are included in Fig. BXII.γ.215. At this time, over 230 16S rDNA sequences have been deposited in GenBank, and 114 nonredundant sequences were selected for inclusion in this tree. The neighbor-joining method (Saitou and Nei, 1987) was used for tree construction. Bootstrap values greater than 40% are shown. It can be seen from the tree that species named *Haemophilus*, *Actinobacillus*, and *Pasteurella* are intermixed throughout the tree. If the family is to be divided into phenotypically consistent monophyletic groups, then there will need to be about 20 genera in this family. The genus *Mannheimia* is probably the most distinct and well-defined cluster in the family. The delineation of almost every other cluster is somewhat subjective and in almost every case will require additional investigation before the cluster can be proposed as a genus. Because the taxonomy of the *Pasteurellaceae* is in the process of major revision, we felt it useful to present a phylogeny representing as much of the diversity of the family as possible, regardless of whether the taxa have been formally named.

Named genera

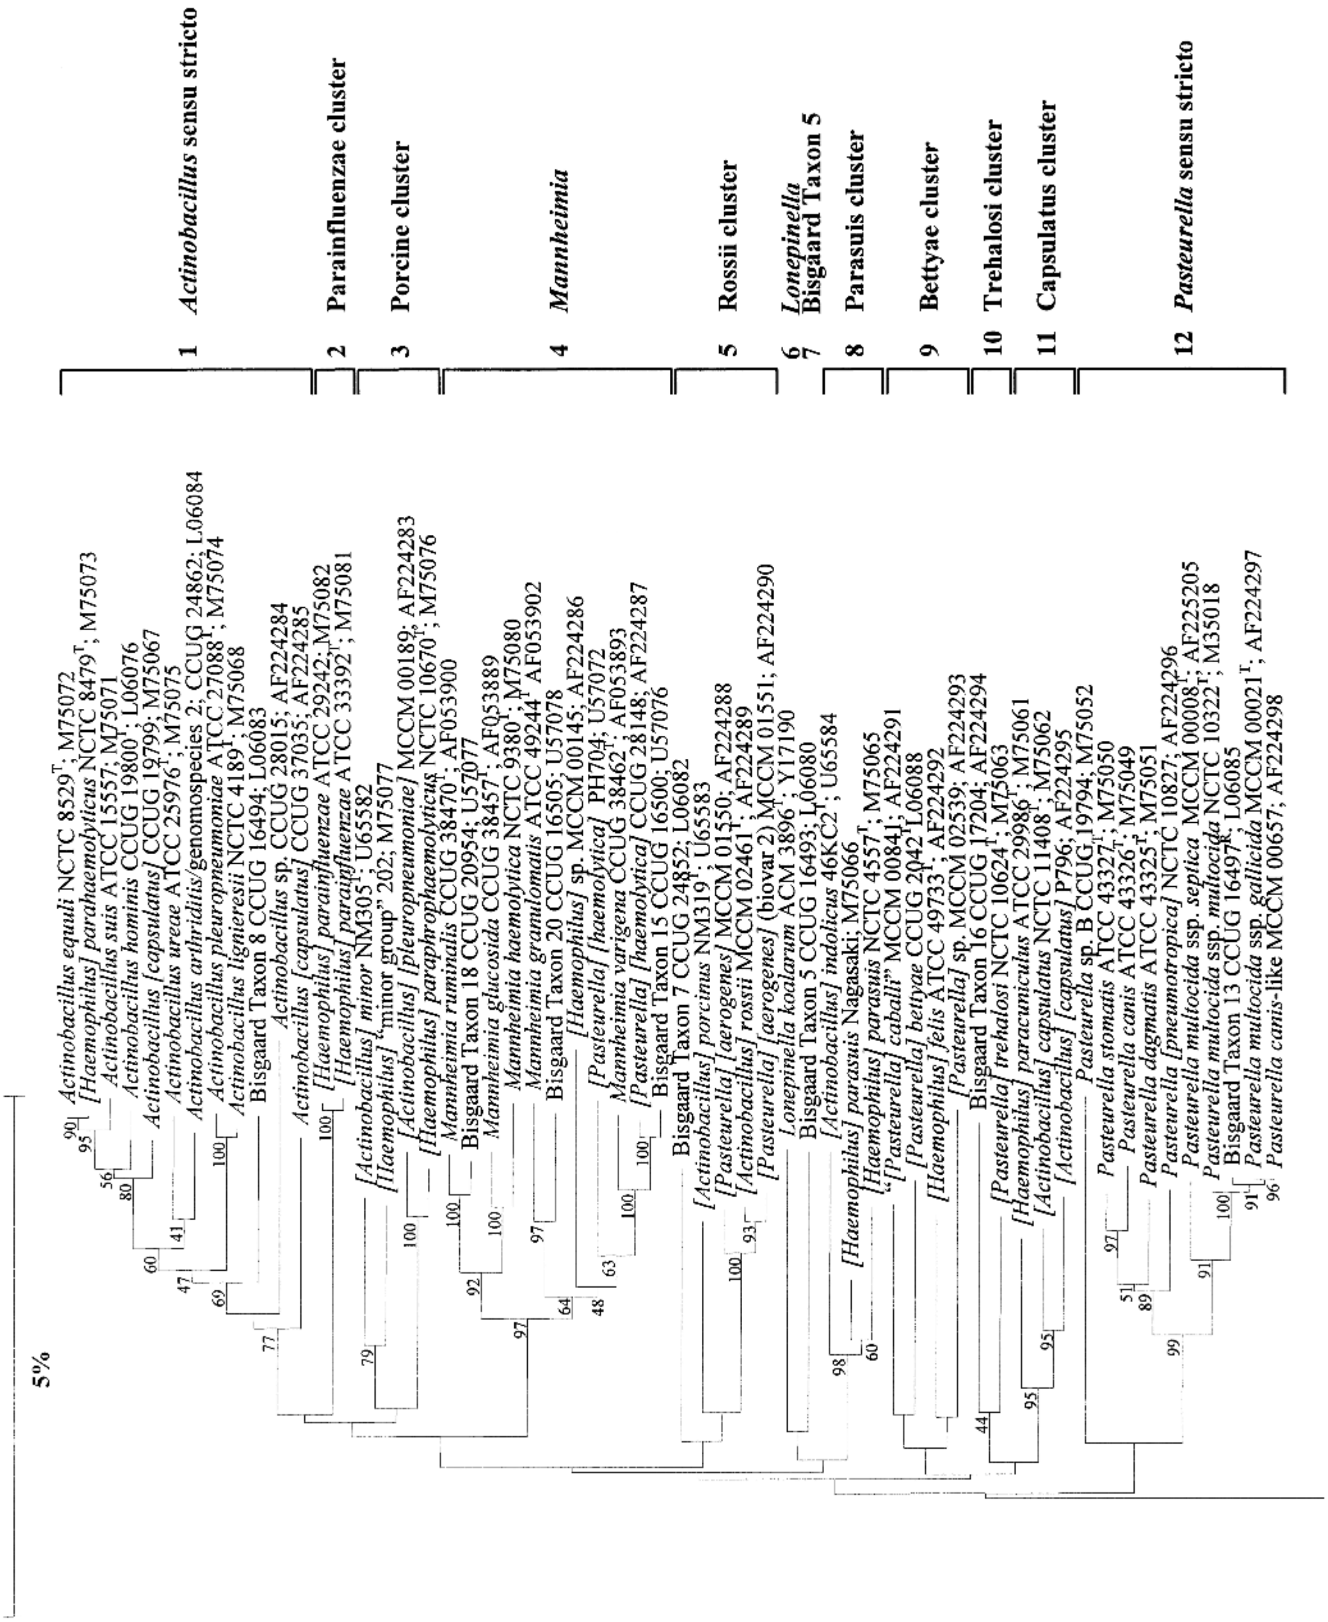
Actinobacillus sensu stricto. The genus *Actinobacillus sensu stricto* should be comprised of the following named species: *A. lignieresii*, *A. pleuropneumoniae*, *A. ureae*, *A. hominis*, *A. equuli*, and *A. suis*. *A. arthritidis* (Bisgaard Taxon 9), Bisgaard Taxon 8, and taxa represented by strains Kunstyr 570 (MCCM 00149), Bisgaard F64 (CCUG 28015), and SSI P585 (CCUG 19799) should be included. This is in general agreement with the proposal of Escande et al. (1984) and Mutters et al. (1989) that the genus *Actinobacillus* should be limited to *A. lignieresii*, *A. equuli*, *A. capsulatus*, *A. suis*, *A. hominis*, *A. pleuropneumoniae*, *A. arthritidis*, and Bisgaard's taxa 5 and 11. 16S rDNA sequencing data suggest addition of *H. parahaemolyticus* and *A. hominis* (Dewhirst et al., 1992, 1993). The type strain of *A. capsulatus* does not cluster with true actinobacilli (Dewhirst et al., 1992, 1993). See discussion under Capsulatus Cluster, below. Bisgaard Taxon 5 falls elsewhere in the tree.

Mannheimia. This genus was recently created from strains that had previously been classified as *Pasteurella haemolytica* (Angen et al., 1999a). Five species have been named: *Mannheimia haemolytica*, *M. glucosida*, *M. granulomatis*, *M. ruminalis*, and *M. varigena*. There are strains representing at least two additional *Mannheimia* species.

Lonepinella. A species isolated from koalas has been given the name *Lonepinella koalarum*.

Pasteurella sensu stricto. The genus *Pasteurella sensu stricto* should be limited to the species *P. multocida*, *P. dagmatis*, *P. canis*, and *P. stomatis*. The three *P. multocida* subspecies are nearly identical by 16S rDNA sequences. Avian species that were previously included by DNA–DNA hybridization studies appear to fall into a separate genus level cluster (see Avian Cluster, below). Bisgaard Taxon 13 strain CCUG 16497 appears to be *P. multocida*. A strain identified as *P. pneumotropica* (NCTC 10827) is not related to the type strain (Rodent Cluster) and appears to represent a novel species in the genus. *Pasteurella* species B branches substantially deeper than do other members of the genus but may warrant inclusion in the genus.

The quinone content of strains of the genus *Pasteurella*, including *P. avium*, *P. canis*, *P. dagmatis*, *P. gallinarum*, *P. langaa*, *P. multocida*, *P. stomatis*, *P. volantium*, *"Pasteurella leonis"*, *Pasteurella* species A, and *Pasteurella* species B, has been reinvestigated (Kainz et al., 2000), with cells grown in liquid PPLO broth under strictly aerobic conditions. Based on the quinone composition, the species could be grouped into two clusters. Cluster I, consisting of the species *P. avium*, *P. gallinarum*, *P. volantium*, and *Pasteurella* species A, was characterized by the two predominant compounds ubiquinone Q-7 and Q-8. These species correspond to the Avian Cluster in Fig. BXII.γ.215. Cluster II, consisting of the species *P. canis*, *P. dagmatis*, *P. langaa*, *P. multocida*, *P. stomatis*, and *Pasteurella* species B, contained only ubiquinone Q-8 as the major compound and corresponds to *Pasteurella sensu stricto* of Fig. BXII.γ.215 (Mutters et al., 1993). These two clusters may be also distinguished by the presence of *sym*-norspermidine in *Pasteurella sensu stricto* (Busse et al., 1997), whereas this triamine has not been detected in representatives of the Avian Cluster in Fig. BXII.γ.215.



Haemophilus sensu stricto. In the previous edition of *Bergey's Manual*, a primary characteristic of the genus *Haemophilus* was X or V-factor requirement. It is now recognized that factor-requiring species are spread throughout the family. Based primarily on the DNA–DNA hybridization data of Burbach (1987), Mutters et al. (1989) proposed restricting the genus *Haemophilus sensu stricto* to include *H. influenzae*, *H. aegyptius*, *H. haemolyticus*, *"H. intermedius"*, and *H. parainfluenzae*. The 16S rRNA tree suggests exclusion of *H. parainfluenzae*. As shown in Fig. BXII.γ.215, strains representing serotype e and f of *H. influenzae* appear distinct from the other serotypes of *H. influenzae*. The tree shows the positions of *"H. intermedius* subsp. *intermedius"*, *"H. intermedius* subsp. *gazogenes"*, and "*H. quentini*".

Phocoenobacter. A bacterium isolated from a porpoise has been given the name *Phocoenobacter uteri*.

Clusters that represent potential additional genera

Parainfluenzae Cluster. *H. parainfluenzae* does not belong in the genus *Haemophilus*, but rather forms its own cluster. The species is known to be heterogeneous and may represent multiple species.

Porcine Cluster. This cluster contains four taxa in two subclusters: *Actinobacillus minor*, *Haemophilus* "minor group" 202, *A. pleuropneumoniae*, and *H. paraphrohaemolyticus*.

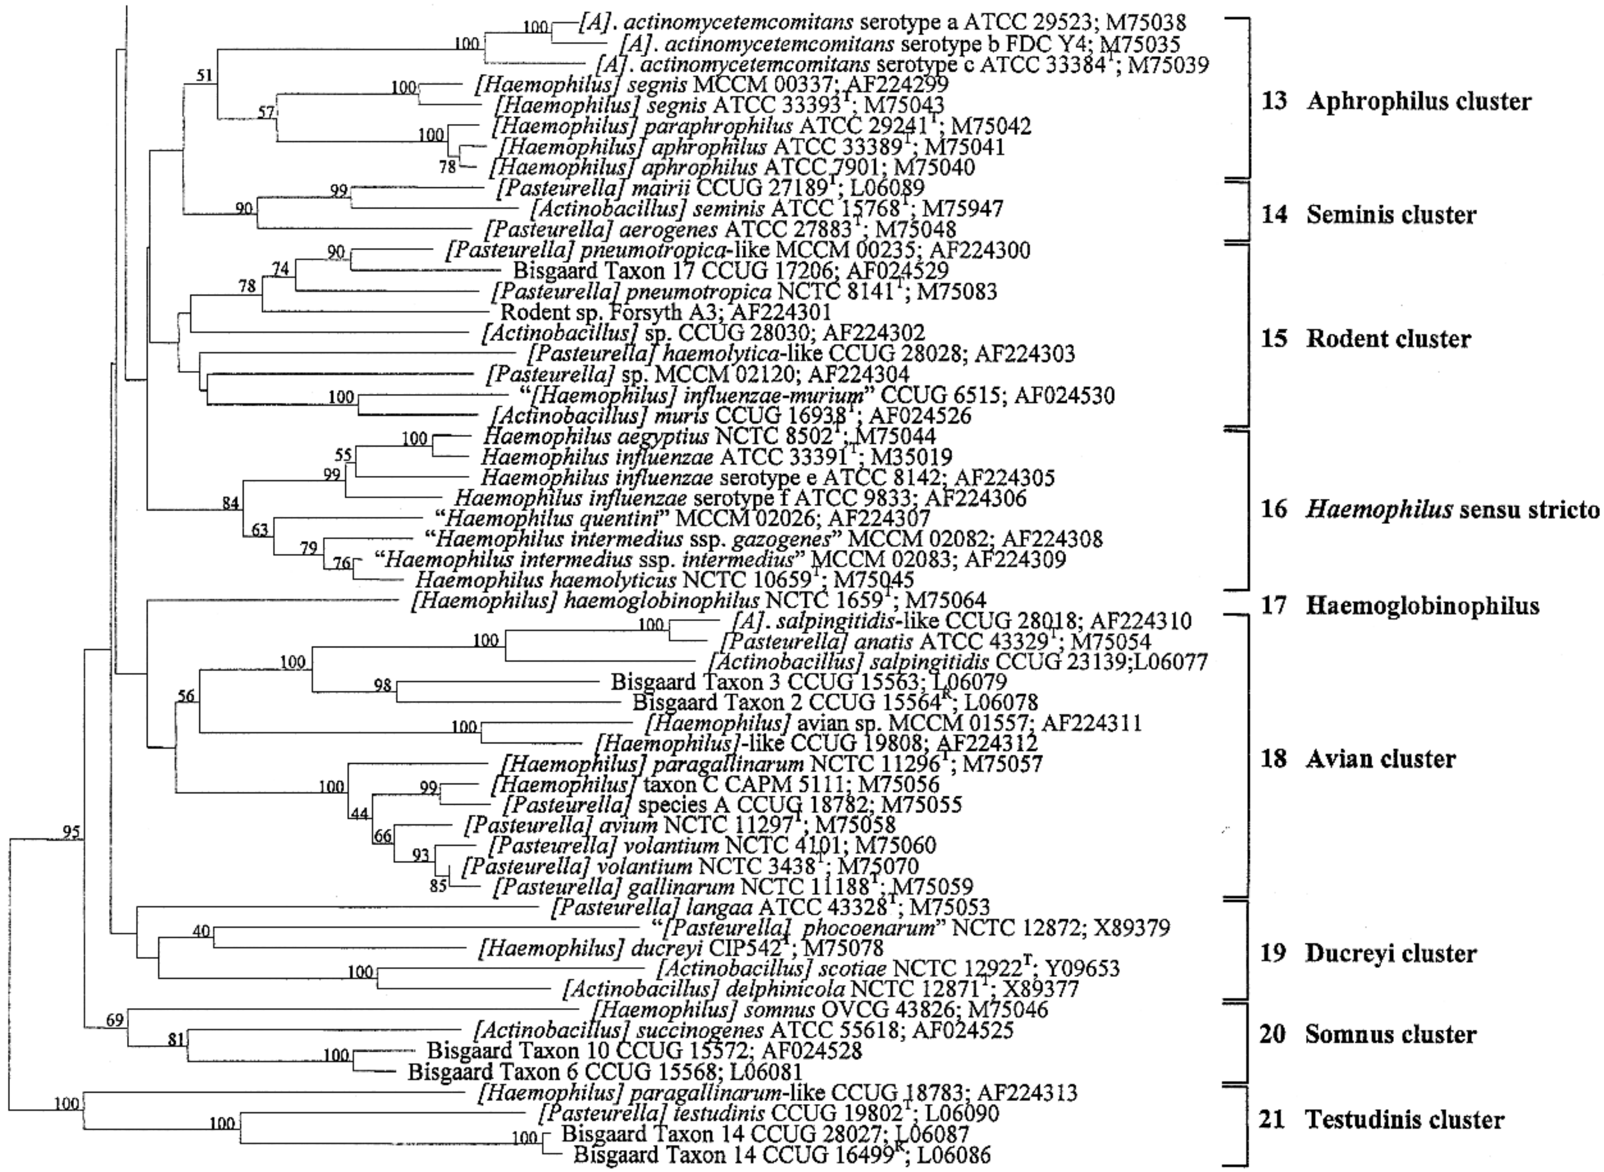

FIGURE BXII.γ.215. Phylogeny of the *Pasteurellaceae*. The family *Pasteurellaceae* forms a coherent phylogenetic subgroup within the *Gammaproteobacteria* that is divided into 21 phylogenetic clusters. Five of the clusters are represented by the named genera *Actinobacillus sensu stricto*, *Haemophilus sensu stricto*, *Pasteurella sensu stricto*, *Mannheimia*, and *Lonepinella*. "*Sensu stricto*" is defined herein as a distinct phylogenetic clade. The remaining clusters contain generically misclassified species of *Actinobacillus*, *Haemophilus*, and *Pasteurella*, as well as unnamed species of *Pasteurellaceae* from a variety of culture collections. A bracket around the genus or specific epithet denotes phylogenetic misclassification. The strain number and GenBank accession number of the 16S rRNA sequence are shown. Abbreviations for culture collections are as follows: ATCC, American Type Culture Collection, Manassas, VA; NCTC, National Collection of Type Cultures, London, England; MCCM, Medical Culture Collection of Microorganisms, Marburg, Germany; CCUG, Culture Collection, University of Göteborg, Göteborg, Sweden; CAPM, Collection of Animal Pathogenic Microorganisms, Brno, Czech Republic; Forsyth, The Forsyth Institute, Boston, MA; CIP, Collection de l'Institut Pasteur, Paris, France; ACM, Australian Collection of Microorganisms, Brisbane, Australia. Bar = 5% difference in nucleotide sequences. 200 bootstrap trees were generated, and bootstrap confidence levels (shown as percentages at the nodes) were determined.

Rossii Cluster. This cluster includes *Actinobacillus rossii*, *A. porcinus*, and strains that are considered part of the *Pasteurella aerogenes* complex, but do not fall with the type strain, which is in the Seminis Cluster. The Rossii Cluster may also include the more deeply branching Bisgaard Taxon 7, but this taxon is somewhat unstable in its branching position within the tree. See discussion for Bisgaard Taxon 5.

Bisgaard Taxon 5. The phylogenetic position of this taxon is problematic in that its position in the tree is unstable. Changes of taxa included in the analysis cause Bisgaard Taxon 5 to jump from place to place in the tree. Molecular data from other genes may be required to define its true position.

Parasuis Cluster. This cluster includes *H. parasuis*, *A. indolicus*, and a third taxon represented by *H. parasuis* strain Nagasaki.

Bettyae Cluster. This cluster includes *P. bettyae*, *"P. caballi"*, *H. felis*, and guinea pig conjunctivitis strain Stenzel T 391 (HIM 1028-4).

Trehalosi Cluster. *P. trehalosi* forms a cluster with Bisgaard Taxon 16. It may be possible to join the Trehalosi and Capsulatus Clusters.

Capsulatus Cluster. This cluster includes *A. capsulatus*, *H. paracuniculus*, and a third taxon represented by *A. capsulatus* strain SSI P796. The taxonomic position of *A. capsulatus* has been controversial because DNA–DNA hybridization placed it with *Actinobacillus sensu stricto* (Escande et al., 1984; Mutters et al., 1989). However, sequences for five isolates (SSI P243^T, P244, P572, P662, and P796) all fall in the Capsulatus cluster. The horse isolate, SSI P585(CCUG 19799), falls in the middle of the *Actinobacillus sensu stricto* cluster, and if DNA from this strain was inadvertently used in place of that of the type strain (SSI P 243), it could explain the older DNA–DNA hybridization results. A hamster *"A. capsulatus"* strain, MCCM 149, branches with a duck isolate, Bisgaard F64 (CCUG 28015), to form the deepest branch of the *Actinobacillus sensu stricto* cluster. It would appear that *A. capsulatus*-like strains from species other than rabbit represent multiple unique species.

Aphrophilus Cluster. This cluster includes *H. segnis*, *H. aphrophilus*, *H. paraphrophilus*, and an *H. segnis*-like taxon represented by strain MCCM 00337. Based on rRNA–DNA hybridizations, De Ley et al. (1990) suggested that the Aphrophilus cluster be split off from the *Haemophilus sensu stricto*. We would suggest including *A. actinomycetemcomitans* in this cluster to be consistent with the DNA–DNA hybridization data of Potts et al. (1985).

Seminis Cluster. This cluster includes *A. seminis*, *P. mairii*, and *P. aerogenes*. Other strains of the *P. aerogenes* complex, such as the Rossii Cluster, fall elsewhere in the tree.

Rodent Cluster. This genus level cluster includes nine species, all isolated from rodents or guinea pigs. Named species include *P. pneumotropica*, *A. muris*, and *"H. influenzae-murium"*. Also included are Bisgaard Taxon 17 (rat), strain Kunstyr 507 (MCCM 02120 [hamster]), Mannheim Michael A (CCUG 28028 [guinea pig]), Kunstyr 246 (CCUG 28030 [hamster]), Mannheim A/5a (MCCM 00235 [rat]), and Forsyth A3 (mouse). This large cluster clearly warrants further investigation for promotion to genus status.

Haemoglobinophilus Cluster. This cluster contains the single species *H. haemoglobinophilus*.

Avian Cluster. *P. volantium*, *P. gallinarum*, and *P. avium* were placed in the *Pasteurella sensu stricto* based on DNA–DNA hybridization (Pohl, 1981a), but by 16S rDNA sequence analysis, they fall into a large cluster of avian species quite distant from the *Pasteurella sensu stricto*. This avian cluster also includes *"Actinobacillus salpingitidis"*, *P. anatis*, *H. paragallinarum*, Bisgaard Taxon 2, Bisgaard Taxon 3, *Haemophilus* taxon C, *Pasteurella* species A, and strains representing additional species such as Wuthe DS 1801 (MCCM 01557), *"A. salpingitidis"* CCUG 28018, and *Haemophilus* sp. CCUG 19808. Members of the subcluster consisting of *P. avium*, *P. gallinarum*, *P. volantium*, *Pasteurella* species A, and H. paragallinarum contain a polyamine pattern with the predominant compounds 1,3-diaminopropane and spermidine. Strains of Bisgaard Taxon 2 and Taxon 3 are characterized by polyamine patterns with the major compounds putrescine and spermidine (Taxon 2) and putrescine, cadaverine, and spermidine (Taxon 3). The third subcluster, consisting of two strains of *"A. salpingitidis"* and *P. anatis*, contain either the predominant compounds 1,3-diamonipropane and spermidine or additionally putrescine (Busse et al., 1997).

Ducreyi Cluster. This cluster includes *H. ducreyi*, *P. langaa*, and the three cetacean species *A. delphinicola*, *A. scotiae*, and *"P. phocoenarum"* (now *Phocoenobacter uteri*).

Somnus Cluster. This cluster includes *"Haemophilus somnus"*, *A. succinogenes*, Bisgaard Taxon 6, and Bisgaard Taxon 10.

Testudinis Cluster. This cluster is the most deeply branching of the family *Pasteurellaceae*. It contains *P. testudinis*, Bisgaard Taxon 14, and the *H. paragallinarum*-like strain CCUG 18783. This cluster is distinct from the rest of the *Pasteurellaceae* in having the common *Proteobacteria* signature 665 A rather than the *Pasteurellaceae* signature 665 G.

The resolution of 16S rDNA sequence analysis may be inadequate to delineate the deeper phylogenetic branching in the *Pasteurellaceae*. Multi-gene sequence analysis has been used effectively to type species (Maiden et al., 1998). Similar methods can also be used to examine species- and genus-level relationships. With the complete genome of *H. influenzae* as well as extensive information for the unfinished genomes of *A. actinomycetemcomitans* and *P. multocida* available, it is reasonably easy to design primers to amplify and sequence essentially any chosen gene. Additional phylogenetic studies using genes such as *recA*, *dnaJ*, or *fur* may provide sufficient information to resolve the deeper branches in the family *Pasteurellaceae*. Phylogenetic analysis of genes other than 16S rRNA would also provide a valuable check on whether the 16S tree represents a consensus species tree, or only an evolutionary tree for one specific gene. Examination of local gene order may also be useful for defining genera. While molecular data will no doubt be the primary basis for resolving taxonomic issues, a polyphasic approach to describing the genera is essential. Promising phenotypic traits that could aid taxonomic analysis are polyamine patterns, quinone composition, and carbohydrate profiles.

Genus I. **Pasteurella** *Trevisan 1887, 94^AL Nom. Cons. Opin. 13, Jud. Comm. 1954b, 153*

REINIER MUTTERS, HENRIK CHRISTENSEN AND MAGNE BISGAARD

Pas.teu.rel′ la. M.L. dim. fem. n. *Pasteurella* named after Louis Pasteur.

Coccobacilli or rods, generally, 0.3–1.0 × 1.0–2.0 μm. Depending on the growth stage, cells occur singly, in pairs, or less frequently in short chains. Sometimes threads or filaments are formed resulting in marked pleomorphism. Pleomorphism occurs mainly in old cultures. **Gram negative**, although **bipolar staining often can be observed**. In tissues, *P. multocida* often shows bipolar staining with Giemsa or Wright's stain. Not acid fast. **Endospores are not formed. Nonmotile. Aerobic to microaerophilic or facultatively anaerobic.** Chemoorganotrophic with both oxidative and fermentative types of metabolism. Electron transport system is cytochrome-based with oxygen, nitrate, or fumarate as the terminal electron acceptor. **Nitrate reductase is produced. Oxidase positive, alkaline phosphatase positive**, and almost always **catalase positive**. **Most species are V-factor and X-factor independent, but V-factor-requiring strains do occur.** Even after specific growth factors have been provided, **complex media may be required to obtain better growth**. Optimum growth temperature 35–37°C. Arginine dihydrolase and lysine decarboxylase negative. Gelatin is not liquefied within 48 h. No growth occurs in Simmons citrate medium. Acid is produced from D-glucose, D-galactose, D-fructose, D-mannose, and sucrose. Acid is not produced from L-sorbose, L-rhamnose, *m*-inositol, and adonitol. Parasitic in vertebrates, particularly mammals and birds. Genome molecular weights range from 1.4×10^9 to 1.9×10^9.

The mol% G + C of the DNA is: 37.7–45.9.

Type species: **Pasteurella multocida** (Lehmann and Neumann 1899) Rosenbusch and Merchant 1939, 85 (*Bacterium multocidum multocidum* (sic) Lehmann and Neumann 1899, 196; *Pasteurella gallicida* (Burrill 1883) Buchanan 1925, 414.)

FURTHER DESCRIPTIVE INFORMATION

Phylogeny Based on 16S rDNA sequence comparison of selected strains, the genus was separated into two phylogenetic groups (Dewhirst et al., 1992, 1993). The core group around the type species included the other species from mammalian hosts: *P. canis*, *P. stomatis*, *P. dagmatis*, and *Pasteurella* sp. B. The avian species *P. avium*, *P. gallinarum*, *P. volantium*, and *Pasteurella*. sp. A form a separate cluster together with the type strain of *Haemophilus paragallinarum*. Based on 16S rRNA sequences *P. langaa* and *P. anatis* were not phylogenetically related to the other *Pasteurella* species at the genus level.

Cell wall composition The cell wall and the lipopolysaccharide (LPS) composition of *P. multocida* were comparable to most Gram-negative bacteria and contained lipid A, 2-keto-3-deoxyoctonate, L-glycero-D-mannoheptose, glucose, and glucosamine, and might contain galactose, rhamnose, D-glycero-D-mannoheptose, and galactosamine (Rimler and Rhoades, 1989). Polyamine analysis showed members of the genus *Pasteurella* to possess 1,3-diaminopropane, putrescine, cadaverine, spermidine, and spermine, and for some species *sym*-norspermidine in the cell wall. The unusual triamine *sym*-norspermidine was found only in *P. multocida*, *P. canis*, *P. dagmatis*, *P. stomatis*, and *Pasteurella* sp. B, but not in other *Pasteurellaceae*. This character is specific for the 16S rRNA subcluster 12 of Olsen et al. (see Fig. BXII.γ.215 of the chapter describing the family *Pasteurellaceae*, this *Manual*). Species of *Pasteurella* in 16S rRNA cluster 18 contained 1,3-diaminopropane and spermidine. In accordance with the 16S rRNA analysis, the polyamine pattern of the remaining species of *Pasteurella* diverged from these two groups. *P. anatis* diverged from species of 16S rRNA cluster 18 by high putrescine content (Busse et al., 1997). The isoprenoid quinone composition of true members of the genus *Pasteurella* exhibits high amounts of quinones with the chain length eight: ubiquinone Q-8, menaquinone MK-8, and demethylmenaquinone DMK-8 (Mutters et al., 1993).

The capsule of *P. multocida* is composed of carbohydrates and is very hydrophilic (Rimler and Rhoades, 1989). The biosynthesis and genetic background of capsule formation has been described recently (Boyce and Adler, 2000).

Hyaluronic acid has been reported in the capsular material and the biosynthesis pathway for hyaluronan has been described for *P. multocida* (DeAngelis, 1999).

Outer membrane proteins (OMPs) OMP analysis by SDS-PAGE has been reported for *P. multocida*. Specific OMP profiles of the 16 different serotypes were not given and it was found that *in vivo* propagation led to the expression of additional OMPs (Choi et al., 1989a). The expression of OMP by *P. multocida* was found to be influenced by iron and, in particular, molecules of 76, 84, and 94 kDa were expressed under iron-restricted conditions (Choi-Kim et al., 1991; Zhao et al., 1995). A 37.5-kDa porin of *P. multocida* affected bovine neutrophils (Galdiero et al., 1998). In *P. testudinis*, iron regulated OMPs were also identified (Snipes et al., 1995). Cross-reaction was found between iron-regulated OMPs in pigs and fowl (Zhao et al., 1995). Strains of *P. trehalosi* representing the four serotypes showed only four OMP profiles by SDS-PAGE electrophoresis; however, substantial diversity was observed between OMP profiles of *M. haemolytica* and *P. trehalosi* (Davies and Quirie, 1996), confirming the reclassification of the two taxa at the genus level (see *Mannheimia* chapter).

Monoclonal antibodies raised against different OMPs of *P. multocida* were able to specifically detect strains of capsular type D of *P. multocida* or of the species *P. stomatis*, *P. gallinarum*, *P. bettyae*, *Pasteurella* sp. B, and *P. canis* but not other Gram-negative bacteria, suggesting variable levels of epitope specificity (Marandi and Mittal, 1995, 1996). A relationship between *P. multocida*, *P. gallinarum*, *Haemophilus paragallinarum*, *P. volantium*, and *P. avium* was inferred through the binding of a polyclonal antibody raised against a putative porin of *P. multocida*. The *N*-terminal amino acid sequence confirmed relationships to other Gram-negative bacteria and to members of *Pasteurellaceae* in particular (Lubke et al., 1994; Hartmann et al., 1996).

Outer membrane proteins and capsular material including hyaluronic acid of serotype A have been characterized and are probably associated with virulence by interacting with host immune system (Rimler and Rhoades, 1989; Boyce and Adler, 2000; Hunt et al., 2000).

Lipopolysaccharides (LPS) LPS of 13 Heddleston serotypes of *P. multocida* all contained glucose, 2-keto-3-deoxyoctonate, and heptose. Two isomers of heptose were found in serotypes 2 and 5. Rhamnose was identified with LPS of serotype 9 and galactose found in all serotypes except serotype 11 (Rimler et al., 1984; Conrad et al., 1996). A strain of serotype 8 contained galactose also and heptose. The amino sugars galactosamine, glucosamine, glucosamine-6-phosphate, and 3-deoxy-*d*-manno-2-octylosonic ac-

id were found in a strain of serotype 8 (Conrad et al., 1996). SDS-PAGE analysis of the serotypes of *P. multocida* showed similarities but not identity. Capsulation did not affect the LPS profile (Rimler, 1990). Purified LPS of *P. multocida* was found to cause suppurative airsacculitis, pleuritis, and pneumonia in turkeys (Kunkle and Rimler, 1998). LPSs of *P. multocida* capsular type A were found to affect the humoral and cell-mediated immune response (Maslog et al., 1999). Similar to the analysis of OMP, high homogeneity of LPS profiles was found within *P. trehalosi* by SDS-PAGE electrophoresis. (Davies and Quirie, 1996).

Fatty acids The dominant fatty acids in *P. multocida* serotype 8 were 3-hydroxytetradecanoate and tetradecanoate (Conrad et al., 1996) and *P. multocida* could be distinguished from other Gram-negative bacteria by the presence of $C_{14:0\ 3OH}$ (Dees et al., 1981). The fatty acids $C_{14:0}$, $C_{16:1}$, $C_{16:0}$, $C_{14:0\ 3OH}$, $C_{18:2}$, $C_{18:1}$, and $C_{18:0}$ were found in human strains of *P. multocida* subsp. *multocida*, *P. multocida* subsp. *septica*, *P. canis*, *P. stomatis*, and *P. dagmatis*; however, a differentiation of these species was not possible on the basis of fatty acid analysis. (Holst et al., 1992). The fatty acid profiles of the species of the family *Pasteurellaceae* proved to be indistinguishable (Mutters et al., 1993). The growth medium was found to affect the fatty acid profiling of members of *Pasteurella* (Boot et al., 1999).

Fine structure Type 4 fimbriae and the corresponding genes of representative serovars of *P. multocida* have been characterized (Ruffolo et al., 1997; Doughty et al., 2000). Pili of rigid and curly types have been observed on both capsulated and noncapsulated strains of *P. multocida* (Rebers et al., 1988; Isaacson and Trigo, 1995).

Colonial and cultural characters On standard agar plates for fastidious Gram-negative bacteria like chocolate agar or Columbia blood agar, *Pasteurella* mostly appear as regular, smooth, convex, grayish, nontransparent, circular colonies. The colonies are generally small with a diameter of 0.5–2 mm after 24 h incubations at 37°C. β-hemolysis on bovine or ovine blood agar is not seen, but a greenish discoloration may occur. Occasionally, yellowish-pigmented colonies can be seen, a phenomenon that is commonly associated with strains of *P. dagmatis* and *P. canis*. Isolates of *P. multocida* from the respiratory tract of ruminants, pigs, and rabbits may form large, watery, mucoid colonies that may collapse after 48 h incubation. Growth in broth usually causes turbidity, but granular growth may occur.

Nutrition and growth conditions Growth requirements of *P. multocida* have been reviewed by Rimler and Rhoades (1989). Cysteine, nicotinamide, pantothenate, and thiamine were required for growth. Apart from these specific growth factors, the different species of *Pasteurella* seem to exhibit variation in nutritional needs and preferred growth conditions. Systematic investigations based on international reference strains, however, do not exist.

V-factor requirement, usually described as nicotinamide adenine dinucleotide (NAD), has been reported for *P. avium*, *P. volantium*, *Pasteurella* sp. A (Mutters et al., 1985b), and *P. multocida* subsp. *multocida* (Krause et al., 1987). Occurrence of V-factor-independent isolates of *P. avium*, *P. volantium*, and *Pasteurella* sp. A have subsequently been reported by Bisgaard (1993), Bragg et al. (1997), and Bisgaard et al. (1999). However, none of these isolates was shown to belong to the respective species based on genetic characterization. Sources of V-factor and demonstration of V-factor requirement is discussed elsewhere (see *Haemophilus* chapter). The temperature range for growth is 22–44°C, with an optimum growth temperature of 35–37°C. Increased carbon dioxide may be required for surface growth of certain isolates. Metabolic pathways have been investigated for *P. multocida* and reviewed by Rimler and Rhoades (1989).

Genetics The genomic sequence was determined in the avian strain Pm 70 of *P. multocida* and found to be 2,257,487 bp long with 2014 predicted coding regions (May et al., 2001). Strains of *P. multocida* have been found to possess six (Liu et al., 1999; May et al., 2001) or five (Hunt et al., 1998) ribosomal operons. Similar, but not identical, genome structure, was determined by I-*Ceu*I restriction analysis; however, a few bovine strains diverged (Liu et al., 1999). Few genes have been characterized and those exclusively in *P. multocida*. The catabolic pathways for asparagine, histidine, leucine, lysine, and phenylalanine were absent from the *P. multocida* genome (May et al., 2001).

Virulence genes Best understood is the formation and activity of the dermonecrotic toxin found in some representatives of capsular types A and D of *P. multocida* that cause atrophic rhinitis in pigs (Hunt et al., 2000). Other virulence factors are incompletely understood in *P. multocida*, the only species studied in more detail. Two gene regions showed homology to the filamentous hemagglutinin gene of *Bordetella pertussis*, coding for proteins important in host cell binding and immunity (Fuller et al., 2000; May et al., 2001). In addition, virulence genes were identified homologous to hemolysin, hemolysin-binding protein, secretion accessory protein, Ton-dependent transport, and adherence (Fuller et al., 2000). Genes of the RTX toxin gene family have not been found except in *P. aerogenes* (Kuhnert et al., 1997). The gene cluster coding for leukotoxin has been found in all serotypes of *P. trehalosi* and the sequence of *lktA* characterized in detail (Shewen and Wilkie, 1982; Burrows et al., 1993; Davies et al., 2001). Capsulation and piliation are potential virulence factors whose genes have been characterized (Boyce and Adler, 2000; Doughty et al., 2000).

Plasmids and transposons Plasmids of 1.3–100 kb have been found in *P. multocida* (Hunt et al., 2000). Plasmids have been found related to resistance to streptomycin, sulfonamides, tetracycline, penicillins, kanamycin, and chloramphenicol (Hunt et al., 2000). The possession of identical nonconjugative R plasmids of *P. multocida* did not follow the clonal population structure (Ikeda and Hirsh, 1990). The only transposable element identified in *P. multocida* has been Tn5706 (Hunt et al., 2000), but Tn10 was able to integrate into the chromosome of *P. multocida* and is important in generating mutants (Lee and Henk, 1996).

Population genetics The population structure of *P. multocida* and *P. trehalosi* have been concluded to be clonal as determined by MLEE (multilocus enzyme electrophoresis), with genetic diversity of between 0.289 and 0.474 (Davies et al. 1997; Blackall et al., 1998; May et al., 2001).

Antigenic structure *P. multocida* has been the subject of numerous antigenic and serologic studies. However, only a few serological typing systems have gained wide acceptance. Four types (I, II, III, and IV) were recognized by Roberts (1947), based on passive protection of mice by serum against live challenge organisms. The most commonly used capsule typing system used so far was developed by Carter (1955). This typing system is based on passive hemagglutination of erythrocytes sensitized by capsule antigen, and five capsule types (A, B, D, E, and F) are presently distinguished (Rimler and Rhoades, 1987, 1989). Presumptive

identification of capsular types A, D, and F by capsule depolymerizations with mucopolysaccharidases has been reported by Rimler (1994). Subsequent cloning and sequencing of the entire capsular biosynthetic loci of *P. multocida* strains X-73 (A:1) (Chung et al., 1998b) and M 1404 (B:2) (Boyce et al., 2000), and nucleotide sequence analysis of the biosynthetic region from each of the remaining three capsule types D, E, and F, identified capsule-specific regions and allowed development of a highly specific multiplex capsular PCR assay (Townsend et al., 2001).

A total of 11 different O or somatic types of *P. multocida*, based on the use of acid-treated cells and agglutinin-absorption procedures, were reported by Namioka (1978). A more commonly used system for somatic antigen typing based on gel diffusion precipitin tests was developed by Heddleston et al. (1972). Sixteen serotypes (1–16) were recognized by Heddleston et al. (1972). Serological typing of *P. multocida* has been reviewed and discussed by Rimler and Rhoades (1989). Comparative studies by Brogden and Packer (1979) indicated that a serotype determination by one method did not correlate with serotyping by other methods. The relationship between subspecies and serovars of *P. multocida* obtained by published serotyping systems remains to be elucidated. Average linkage cluster analysis of precipitate values obtained by crossed immunoelectrophoresis revealed a close antigenic relationship between species of the genus *Pasteurella* as defined by Mutters et al. (1985a, b). Avian and mammalian species clustered separately, just as *P. anatis* and *P. langaa* made up a separate cluster (Schmid et al., 1991), confirming subsequent 16S rDNA similarity studies. The immunogens of *Pasteurella* have been reviewed by Confer (1993).

Antibiotic sensitivity Minimum inhibitory concentrations (MICs) of selected antimicrobial agents have been reviewed by Rimler and Rhoades (1989). Most human isolates of *Pasteurella* are susceptible to penicillin (Holst et al., 1992), the antibiotic of choice for local wound infections. Other β-lactam antibiotics should be effective as well, although in the case of the carbapenems, meropenem was more active than imipenem (Jorgensen et al., 1991). Macrolides and, especially for urinary and respiratory infections, fluoroquinolones such as ciprofloxacin appear to be useful in human and animal infections (Gaillot et al., 1995; Hanan et al., 2000). Most strains are also susceptible to tetracyclines (Holst et al., 1992). Marbofloxacin, a fluoroquinolone exclusively for veterinary use could be useful in the treatment of diseases in dogs and cats (Spreng et al., 1995). Tilmicosin, a macrolide antibiotic for use in veterinary medicine, proved to be effective in the treatment of pasteurellosis in rabbits (McKay et al., 1996).

Ecology With the exception of certain strains of *P. multocida*, organisms classified as *Pasteurella* are usually regarded as opportunistic pathogens that may colonize and form part of the indigenous flora of the mucous membranes of the upper respiratory and lower genital tracts.

Although numerous investigations have been carried out to determine the prevalence of these organisms, lack of sensitive and specific tests for their isolation and identification have prevented insight into their real distribution (Bisgaard, 1993). Previous investigations have mainly focused on the respiratory tract. Detection of a high proportion of cloacal carriers in poultry of *P. multocida* (Muhairwa et al., 2000) emphasizes the importance of sampling mucosal membranes other than the respiratory tract.

P. multocida is distributed worldwide among terrestrial as well as aquatic species of mammals and birds, and any species of these groups should be considered as a possible host. Although the host spectrum seems very large compared to other *Pasteurellaceae*, indications also exist that certain subtypes have developed, the disease potential of which seems to be limited to only a few species (see pathogenicity).

P. canis biovar 1, *P. stomatis*, *P. dagmatis*, and *Pasteurella* sp. B are mainly associated with the oral and nasal mucosa of dogs and cats (Bisgaard, 1993; Ganiere et al., 1993; Muhairwa et al., 2001). However, isolates of *P. dagmatis* from rodents and a scarlet macaw have also been reported (Bisgaard, 1993; Bisgaard et al., 1999). These isolates, however, remain to be characterized genetically.

P. gallinarum is normally associated with different pathological lesions in poultry, and its occurrence in healthy birds remains to be investigated (Bisgaard, 1993). A single isolate has been reported from a healthy duck (Muhairwa et al., 2001). Publications on isolation from animal species other than birds should be questioned (Bisgaard and Mutters, 1986a; Boot and Bisgaard, 1995; Frederiksen and Tønning, 2001). The natural habitats of the remaining species of *Pasteurella* belonging to the 16S rRNA cluster 18 of Olsen et al. (see Fig. BXII.γ.215 of the chapter describing the family *Pasteurellaceae*, this *Manual*) seem to be associated with birds only. Isolates of *P. avium* biovar 2 associated with pneumonia in cattle should be reinvestigated, since recent investigations have shown that nearly identical 16S rDNA sequences were observed for *P. multocida* and biovars 2 of *P. canis* and *P. avium* (Christensen et al., unpublished results). *P. multocida* and biovar 2 of *P. canis* and biovar 2 of *P. avium* also expressed similar OMP profiles (Abdullahi et al., 1990).

Pathogenicity Among species classified as *Pasteurella*, *P. multocida* has been recognized as an important veterinary pathogen for more than a century. It causes a wide range of diseases in animals. Capsule type A serotypes 1, 3, and 4 are recognized as the primary cause of fowl cholera in poultry and wild birds (Rhodes and Rimler, 1989). Disease may appear as an acute septicemia characterized by disseminated intravascular coagulation, petecchial or ecchymotic hemorrhages, multifocal necroses, and fibrinous pneumonia. Chronic infections may involve a variety of local infections (Christensen and Bisgaard, 1997, 2000). *P. multocida* capsule types B and E are associated with hemorrhagic septicemia of cattle, water buffaloes, and occasionally other species, resulting in major economic losses, mainly in Southeast Asia (Carter and De Alwis, 1989; De Alwis, 1995). Respiratory diseases in cattle, including bronchopneumonia in feedlot cattle and enzootic pneumonia of calves less than 6 months old, are mainly associated with capsule type A (Frank, 1989). Outbreaks of septicemia in fallow deer have also been reported (Eriksen et al., 1999). Infections of major economic importance in pigs include atrophic rhinitis and bronchopneumonia (Chanter and Rutter, 1989; Gardner et al., 1994). These syndromes are caused by capsular types A and D. Severe cases of atrophic rhinitis are mainly associated with capsule type D. Pulmonary lesions may result in blood-borne dissemination to the kidneys in pigs (Buttenschøn and Rosendal, 1990). In addition to major diseases in production animals, *P. multocida* is recovered from a wide range of sporadic infections in many other species, including laboratory animals (Manning et al., 1989), dogs and cats (Mohan et al., 1997), and other mammals (DiGiacomo et al., 1989).

Although *P. multocida* has challenged researchers for more than a century, mechanisms behind virulence and pathogenesis have remained unclear, as demonstrated in recent literature (Christensen and Bisgaard, 1997, 2000). Successful isolation of DNA fragments containing the toxin-encoding gene from toxi-

genic *P. multocida* and cloning these into *E. coli* (Petersen and Foged, 1989; Kamps et al., 1990; Lax and Chanter, 1990) significantly improved our understanding of the pathogenesis of atrophic rhinitis. Sequencing of the entire genome of a common avian clone of *P. multocida* (May et al., 2001) provides a foundation for future research into virulence factors and mechanisms of pathogenesis and host specificity of this pathogen that may kill affected animals within 24 h.

P. multocida and other species of the 16S rRNA cluster 12 are considered as zoonotic pathogens (Bisgaard et al., 1994). Most human infections associated with *Pasteurella* species result from animal bites. The species usually observed in these infections are *P. multocida* subsp. *multocida* and subsp. *septica*, *P. canis*, *P. dagmatis*, and *P. stomatis* (Holst et al. 1992; Escande and Lion, 1993; Matsui et al., 1996). Like other opportunistic pathogens, *Pasteurella* species can be associated with different clinical syndromes, i.e., necrotizing fasciitis (Hamamoto et al., 1995), chronic lung abscess (Machiels et al., 1995), endocarditis (Genne et al., 1996), meningitis (Boocock and Bowley, 1995; Armstrong et al., 2000), pulmonary diseases such as pneumonia (Ory et al., 1998), peritonitis (Wallet et al., 2000), septicemia (Greif et al., 1986), periocular abscess and cellulitis (Hutcheson and Magbalon, 1999), and granulomatous hepatitis (Chateil et al., 1998). Usually human infections result from inoculation of animal secretions via bites or direct contact with animals carrying pasteurellae in their normal bacterial flora.

Enrichment and Isolation Procedures

Species of *Pasteurella* are somewhat fastidious and V-factor-requiring species are traditionally isolated on enriched agar media supplemented with 5% serum or blood and cross-inoculated with a *Staphylococcus* or an *Acinetobacter* strain to provide the V-factor. However, in mixed cultures pasteurellae may be overgrown. Strains of *P. multocida* can be obtained from contaminated material by subcutaneous or intraperitoneal inoculation of mice (Muhairwa et al., 2001). After death, cultures are made from the spleen by ordinary methods. Several selective media have been developed for isolation of *P. multocida* (Rimler and Rhoades, 1989; Moore et al., 1994b; Lee et al., 2000a), and transport media have been investigated (Kawamoto et al., 1997). Comparative investigations, however, remain to be performed.

Short-term survival of pasteurellae for about a week is possible on complex solid media like chocolate agar stored at room temperature or preferably at 4°C in a plastic jar or plastic bag to avoid desiccation. In the case of V-factor-dependent pasteurellae, shorter intervals should be used. Cultures will remain viable for years when frozen at −70°C in liquid media such as protease peptone broth containing 20% glucose or glycerol. Recommended procedures for long-term survival also include lyophilization or storage in liquid nitrogen of cells in nutrient broth containing 20% glucose or glycerol. Both techniques preclude selection of mutants that occur during repeated subculturing.

Differentiation of the genus *Pasteurella* from other genera

Pasteurellae (Table BXII.γ.288) share the common features of the family *Pasteurellaceae* (see chapter *Pasteurellaceae*). They do not grow in Simmons citrate medium. Nitrate reduction is positive. No acid is produced from D-adonitol and L-sorbose. They do not contain arginine dihydrolase, but do produce alkaline phosphatase. In contrast to *Yersinia* they are nonmotile at 22°C, and do not grow in the presence of 4.5% NaCl. Differentiation from *Kingella* and other fastidious Gram-negative rods is possible based on several features, including positive tests for oxidase and catalase and acid production from sucrose and other carbohydrates. Distinction from other genera of the family *Pasteurellaceae*, especially from *Actinobacillus*, has been difficult based on the original concepts of these genera. Despite reallocation of species and outlining of new genera as indicated by Olsen et al. (see Fig. BXII.γ.215 of the chapter describing the family *Pasteurellaceae*, this *Manual*), available data indicate that it will still be difficult to divide the family *Pasteurellaceae* into genera that are phenotypically and phylogenetically coherent.

The pattern of typical biochemical characteristics of *Pasteurellaceae*, combined with the common features of *Pasteurella* (see Table BXII.γ.288), describes true pasteurellae. Although the taxonomy of the genus is still under investigation, some phenotypic features can be defined that are useful in discriminating *Pasteurella* from both other named genera and unnamed and not formally recognized genus-like groups within the family *Pasteurellaceae*. True members of the genus never exhibit hemolysis on ordinary media. Oxidase reaction and usually catalase reaction are positive. Normally, gas is not produced from the fermentation of carbohydrates; occasionally, very small amounts of gas can be detected. The sole *Pasteurella* species exhibiting gas production is *P. dagmatis*. Differences in urease and ornithine decarboxylation can also be used for separation of the genera *Pasteurella* and *Actinobacillus*. With the exception of *P. dagmatis*, all pasteurellae are urease negative, whereas all actinobacilli are positive and, with the exception of *P. dagmatis* and *P. stomatis*, all *Pasteurella sensu stricto* (cluster 12 of Olsen et al.; see Fig. BXII.γ.215 of the chapter describing the family *Pasteurellaceae*, this *Manual*) are ornithine positive, whereas actinobacilli are negative. Differences in indole can also be used for separation of genuine pasteurellae (positive) and actinobacilli (negative), but single indole-negative isolates of *P. multocida* occur. Certain carbohydrates, like L-rhamnose and *m*-inositol, are not cleaved. On the other hand, all pasteurellae produce acid from the six-carbon carbohydrates D-glucose, D-fructose, D-mannose, and D-galactose in contrast to many *Haemophilus* and *Actinobacillus* species. Differences in D-mannose and indole separate the genera *Mannheimia* and *Pasteurella*.

Taxonomic Comments

In the mid-1980s, the taxonomy of the genus *Pasteurella* was studied by DNA–DNA hybridization (Mutters et al., 1985a, b). More recently, the genus was investigated in the context of the whole family by 16S rDNA sequencing (see chapter *Pasteurellaceae*). The results of the DNA hybridization studies led to the reclassification of the genus *Pasteurella sensu stricto*. According to this method, *Pasteurella* contains species interrelated at or above a DNA binding level of 55% based on the optical DNA hybridization method (cit. Mutters et al., 1985a). From the six *Pasteurella* species in the last edition of *Bergey's Manual of Systematic Bacteriology* only the type species of the genus, *Pasteurella multocida* and *P. gallinarum*, are recognized as true pasteurellae. *P. multocida* was subdivided in to three subspecies— subsp. *multocida*, subsp. *septica*, and subsp. *gallicida*—according to DNA-binding data and differences in acid production from D-sorbitol and dulcitol; 1.4–2% 16S rRNA sequence variation was found among *P. multocida* subsp. *septica* and *P. multocida* subsp. *multocida* and subsp. *gallicida*, while subsp. *multocida* and subsp. *gallicida* were nearly identical (Boerlin et al., 2000; Petersen et al., 2001). Partial *atpD* DNA sequence comparison confirmed the 16S rRNA results in that the subspecies

of *P. multocida* differed, with *P. multocida* subsp. *septica* diverged the most from the others (Petersen et al., 2001).

The former biotype 6 or dog-type strains of *P. multocida* that contained D-mannitol and D-sorbitol negative strains of *P. multocida* were classified as the new species *P. canis*. Similar to *P. canis*, but ornithine negative, is *P. stomatis*, which proved to be closely related to *P. canis* and the former *Haemophilus avium*. This V-factor-dependent species of avian origin was classified as *P. avium*. Biotype Henriksen strains of *P. pneumotropica* were classified as *P. dagmatis*, *P. canis*, and *P. stomatis*. *P. dagmatis* is mostly isolated from bite wounds, mainly inflicted by dogs. In addition to the avian species, *P. gallinarum* and *P. avium*, three new species from avian hosts were described, the V-factor-dependent *P. volantium* and two V-factor-independent species, *P. langaa* and *P. anatis*. Two species remained unnamed, but were located in the genus, *Pasteurella* species A and *Pasteurella* species B. *Pasteurella* species A resembles a collection of V-factor-dependent strains formerly designated as *Haemophilus avium*-like. Based on DNA–DNA binding data, all these species were classified as *Pasteurella sensu stricto* (Mutters et al., 1985a, b). Based on 16S rRNA sequence data from selected strains, the genus was separated into two phylogenetic groups (Dewhirst et al., 1992, 1993).

The core group around the type species included the other species from mammalian hosts: *P. canis*, *P. stomatis*, *P. dagmatis*, and *Pasteurella* sp. B. The avian species *P. avium*, *P. gallinarum*, *P. volantium*, and *Pasteurella* sp. A form a separate cluster together with the type strain of *Haemophilus paragallinarum*, and reclassification of this group seems justified based on 16S rDNA phylogenetic analysis and the variations in *atpD* DNA sequences (Petersen et al., 2001).

P. langaa and *P. anatis* were not phylogenetically related to any of the present members of the genus, and should be excluded from the genus *sensu stricto*, just as reconsiderations are needed as to exclusion of the other avian taxa.

Both DNA hybridization and rRNA sequence data suggest the exclusion of species from the genus that were listed in the last edition of *Bergey's Manual of Systematic Bacteriology*. *P. ureae* was reclassified as *Actinobacillus ureae* (Mutters et al. 1986), while *P. pneumotropica* forms a large cluster with several new species requiring the rank of at least one new genus (Ryll et al., 1991). The *M. haemolytica* complex of ruminants contains distinct genetic and phenotypic groups. So far seven species have been outlined, five of which were named in the new genus *Mannheimia*. *P. aerogenes* (McAllister and Carter, 1974), *P. bettyae* (Sneath and Stevens, 1990), *P. caballi* (Schlater et al., 1989), *P. mairii* (Sneath and Stevens, 1990), *P. testudinis* (Snipes and Biberstein, 1982), and *P. trehalosi* (Sneath and Stevens, 1990) all represent misnamed pasteurellas.

Further taxa provisionally affiliated with *Pasteurella* based on phenotypic characters, such as the gas-producing SP-group, could not be integrated in the genus.

Differentiation of the species of the genus *Pasteurella*

Allocation of isolates to existing species of *Pasteurella* usually does not present a problem if, as suggested by Bisgaard (1993), extended characterization and reference strains/data are used. If sequencing facilities are available, partial or full sequencing of 16S rRNA genes should be included. Correct allocation to existing taxa and of newly discovered taxa, however, still remains problematic, and cooperation with reference laboratories is recommended. The differential characteristics of species of *Pasteurella* are given in Table BXII.γ.289, while characters used for separation of subspecies of *P. multocida* are shown in Table BXII.γ.290.

TABLE BXII.γ.289. Characters used for separation of *Pasteurella* spp.[a]

Characteristic	*P. multocida*	*P. canis*	*P. dagmatis*	*P. stomatis*	*Pasteurella* sp. B	*P. anatis*	*P. avium*	*P. gallinarum*	*P. langaa*	*P. volantium*	*Pasteurella* sp. A

[a]Symbols: +, 90% or more of the strains positive within 1–2 d; (+), 90% or more of the strains positive within 3–14 d; −, less than 10% of the strains are positive within 14 d; d, 11–89% of the strains are positive.

List of species of the genus Pasteurella

1. **Pasteurella multocida** (Lehmann and Neumann 1899) Rosenbusch and Merchant 1939, 85[AL] (*Bacterium multocidum multocidum* (sic) Lehmann and Neumann 1899, 196; *Pasteurella gallicida* (Burrill 1883) Buchanan 1925, 414.)
mul.to.ci′ da. L. adj. *multus* many; L. adj. suff. *-cidus* from; L. v. *caedere* to kill; M.L. fem. adj. *multocida* many killing, i.e., pathogenic for many species of animals.

Usually forms coccoid cells or short rods on solid media containing blood. Usually bipolar stained in Gram stain. Pleomorphic rods and short filaments can be seen in broth media and older cultures. Many strains produce capsules. Growth on solid media is best on blood containing agar like sheep blood or chocolate agar. Colonies reach a diameter of 1–2 mm with a light grayish color. Mucoid, smooth, and rough colonies are produced. Nonhemolytic. The indole-producing strains exhibit a distinct odor. The optimal growth temperature for avian strains might be as high as 42°C, compared to 36°C for mammalian strains. Growth can be observed in a wide mesophilic range from 25–42°C.

In addition to the features common to all members of the genus, the three subspecies share the following biochemical reactions. Acid usually produced from D-mannitol. Ornithine is decarboxylated. Usually no V-factor requirement, but V-factor-requiring strains may occur occasionally (Krause et al., 1987). Major differences in phenotypic characters have been reported for *P. multocida* (Heddleston, 1976; Biberstein et al., 1991; Bisgaard et al., 1991b; Fegan et al., 1995). The physiological characteristics of the species are presented in Tables BXII.γ.288, BXII.γ.289, and BXII.γ.290. Several typing systems have been developed and applied for epidemiological studies of *P. multocida* (Nielsen and Rosdahl, 1990; Wilson et al., 1993; Blackall et al., 1999b, 2000; Fussing et al., 1999; Loubinoux et al., 1999; Blackall and Miflin, 2000; Bowles et al., 2000; Gunawardana et al., 2000). Strains of the species are isolated from most mammals, including humans and birds, in which a wide range of diseases are reported due to *P. multocida*. The species belong to 16S rRNA cluster 12. The molecular weight of genomic DNA ranges from 1.5×10^9 to 1.9×10^9.

The mol% G + C of the DNA is: 40.8–43.9 (T_m).

Type strain: ATCC 43137, NCTC 10322.

GenBank accession number (16S rRNA): AF294410, M35018.

TABLE BXII.γ.290. Characters used for identification of subspecies of *Pasteurella multocida*[a]

	P. multocida		
Characteristic	subsp. *multocida*	subsp. *gallicida*	subsp. *septica*
Dulcitol	−	+	−
D(−)Sorbitol	+	+	−
L(−)Fucose	d	−	d
Trehalose	d	−	+
α-Glucosidase (PNPG)	d	−	+

[a]Symbols: +, 90% or more of the strains positive; −, 90% or more of the strains negative; d, 11–89% of the strains positive.

a. **Pasteurella multocida** *subsp.* **multocida** (Lehmann and Neumann 1899) Rosenbusch and Merchant 1939, 85[AL] (*Bacterium multocidum multocidum* Lehmann and Neumann 1899, 196; *Pasteurella gallicida* (Burrill 1883) Buchanan 1925, 414.)

Characteristics are those of the species as given above. Differentiated from the other subspecies by its production of acid from D-sorbitol, but not from dulcitol. Other reactions useful in differentiating between the subspecies are shown in Table BXII.γ.290. The species belongs to 16S rRNA cluster 12. The molecular weight of genomic DNA ranges from $1.5–1.7 \times 10^9$.

The mol% G + C of the DNA is: 40.8 to 43.9 (T_m).

Type strain: ATCC 43137, NCTC 10322.

GenBank accession number (16S rRNA): AF294410, M35018.

b. **Pasteurella multocida** *subsp.* **gallicida** Mutters, Ihm, Pohl, Frederiksen and Mannheim 1985a, 319[VP]
gal.li.ci′ da. L. fem. n. *gallina* hen; L. adj. suff. *-cida* kill; M.L. adj. *gallicida* hen killing, referring to pathogenicity for poultry.

Characteristics are those of the species as given above. Differentiation from the other subspecies by its ability to form acid from D-sorbitol and dulcitol. Other reactions useful in differentiating between the subspecies are shown in Table BXII.γ.290. The species belongs to 16S rRNA cluster 12. The molecular weight of genomic DNA ranges from $1.5–1.8 \times 10^9$.

The mol% G + C of the DNA is: 41.2–42.5 (T_m).

Type strain: ATCC 51689, NCTC 10204.

GenBank accession number (16S rRNA): AF224297, AF294412, AF326323.

c. **Pasteurella multocida** *subsp.* **septica** Mutters, Ihm, Pohl, Frederiksen and Mannheim 1985a, 319[VP]

sep' ti.ca. M.L. fem. adj. *septica* poisoning, infecting.

Characteristics are those of the species as given above. Differentiation from the other subspecies by its negative reactions for acid production from D-sorbitol and dulcitol. Other reactions useful in differentiating between the subspecies are shown in Table BXII.γ.290. The species belongs to 16S rRNA cluster 12. The molecular weight of genomic DNA ranges from 1.5–1.6 × 10^9.

The mol% G + C of the DNA is: 41.5–43.5 (T_m).

Type strain: ATCC 51687, NCTC 11995, CIP A125.

GenBank accession number (16S rRNA): AF225205, AF294411, AF326325.

2. **Pasteurella anatis** Mutters, Ihm, Pohl, Frederiksen and Mannheim 1985a, 320[VP]

a.na' tis. L. fem. gen. n. *anas* duck, of a duck.

Cells are coccobacillary. Colonies are circular, smooth, and grayish-white with a diameter of 1.5–2 mm. Nonhemolytic. Strains have no V-factor requirement. They do not decarboxylate ornithine, do not produce indole, and do not hydrolyze urea. Acid is produced from trehalose, D-mannitol, and D-xylose. No acid is produced from L-arabinose, maltose, D-sorbitol, or dulcitol. Members of the species have been isolated from the intestinal and respiratory tracts of ducks. The species belongs to 16S rRNA cluster 18. The molecular weight of genomic DNA ranges from 1.8–1.9 × 10^9.

The mol% G + C of the DNA is: 39.9–42.3 (T_m).

Type strain: ATCC 43329, NCTC 11413.

GenBank accession number (16S rRNA): AF228001, M75054.

3. **Pasteurella avium** (Hinz and Kunjara 1977) Mutters, Piechulla, Hinz, and Mannheim 1985b, 8[VP] (*Haemophilus avium* Hinz and Kunjara 1977, 324.)

a' vi.um. L. fem. gen. pl. n. *avis* bird, of birds.

Coccoid to pleomorphic rods, occurring singly or in short chains. In liquid culture media, filamentous forms can be seen. Colonies on chocolate agar are usually smooth, convex, slightly yellowish or grayish-white. Nonhemolytic. The species exhibits the common biochemical characteristics of *Pasteurella sensu stricto*. Biotype 1 strains require V-factor, while biotype 2 strains, previously reported as the ornithine decarboxylase-negative type of Bisgaard Taxon 13, are V-factor independent. Acid is produced from glucose without gas formation and from D(+)galactose, D(+)mannose, D(−)fructose, and trehalose. No acid is produced from L(+)arabinose, L(+)rhamnose, raffinose, maltose, D(−)mannitol, D(−)sorbitol, or dulcitol. Indole is not produced, ornithine decarboxylase negative. Found in the hearts and infraorbital sinuses of chickens (biovar 1) and in the lungs of calves suffering from pneumonia (biovar 2). The species belongs to 16S rRNA cluster 18. The molecular weight of genomic DNA is 1.9 × 10^9.

The mol% G + C of the DNA is: 43–45 (T_m).

Type strain: ATCC 29546, IPDH 2654.

GenBank accession number (16S rRNA): M75058.

Additional Remarks: The reference strain for biovar 2 is CCUG 16497 (Bisgaard's ornithine negative taxon 13).

4. **Pasteurella canis** Mutters, Ihm, Pohl, Frederiksen and Mannheim 1985a, 320[VP]

ca' nis. L. gen. n. *canis* of a dog.

Colonial morphology resembles that of *Pasteurella multocida*, although biotype 1 colonies of *P. canis* usually reach a diameter of only 1 mm. Nonhemolytic. Growth optimum is 36°C. Strains are V-factor independent. Ornithine decarboxylase positive. Acid is not produced from L-arabinose, raffinose, lactose, maltose, D-mannitol, D-sorbitol, or dulcitol. Urease negative. Biotype 1 strains exhibit positive reactions for indole; biotype 2 strains are indole negative. *P. canis* biotype 1 is recovered mainly from the oral cavities of dogs and is often isolated from dog-bite wounds in humans. Biotype 2 strains have been isolated from pneumoniae from calves. The species belongs to 16S rRNA cluster 12. The molecular weight of genomic DNA ranges from 1.4–1.6 × 10^9.

The mol% G + C of the DNA is: 37.7–39.8 (T_m).

Type strain: ATCC 43326, NCTC 11621.

GenBank accession number (16S rRNA): M75049.

Additional Remarks: The reference strain for biovar 2 is CCUG 16498 (Bisgaard's ornithine positive taxon 13).

5. **Pasteurella dagmatis** Mutters, Ihm, Pohl, Frederiksen and Mannheim 1985a, 319[VP]

dag.ma' tis. Gr. fem. gen. n. *dagma* bite, from a bite.

Cells coccoid or short rods. Colonies on blood containing media are usually smooth and grayish white. Optimal growth temperature is 36°C under aerobic conditions. Nonhemolytic. Does not require V-factors. Produces small amounts of gas from D-glucose; produces acid from maltose. No acid is produced from D-xylose, L-arabinose, D-mannitol, D-sorbitol, and dulcitol. Tests for glycosides are negative. Positive reactions are obtained for indole and urease. Gelatin may be liquefied after more than 14 d of incubation. The biochemical characteristics are shown in Tables BXII.γ.288 and BXII.γ.289. *P. dagmatis* strains have been isolated from dogs and cats, as well as from human local infections resulting from animal bites or from septicemia and endocarditis (Frederiksen, 1989). The species belongs to 16S rRNA cluster 12. The molecular weight of genomic DNA ranges from 1.5–1.7 × 10^9.

The mol% G + C of the DNA is: 38.9–41.5 (T_m).

Type strain: ATCC 43325, NCTC 11617.

GenBank accession number (16S rRNA): M75051.

6. **Pasteurella gallinarum** Hall, Heddleston, Legenhausen and Hughes 1955, 604[AL]

gal.li.na' rum. L. fem. gen. pl. n. *gallina* hen, of hens.

Cells are coccoid to rod shaped; bipolar staining occurs. Colonies on blood containing solid media are circular, smooth, and convex with a grayish appearance and reach diameters of 1.5 mm. Nonhemolytic. Not V-factor dependent. Optimal growth temperature is 36°C. Produce acid from maltose and trehalose. No acid is produced from D-mannitol, D-sorbitol, dulcitol, and L-arabinose. Tests for ornithine decarboxylase, indole formation, and urease are negative. Production of acid from *meso*-inositol may occur. *P. gallinarum* is isolated from different lesions in fowl. The

species belongs to 16S rRNA cluster 18. The molecular weight of genomic DNA ranges from 1.5–1.6 × 10^9.

The mol% G + C of the DNA is: 41.2–44.8 (T_m).

Type strain: ATCC 13361.

GenBank accession number (16S rRNA): M75059.

7. **Pasteurella langaa** Mutters, Ihm, Pohl, Frederiksen and Mannheim 1985a, 320[VP]

lan' gaa. L. fem. n. *langaa* referring to the village of Langaa in Denmark.

Cells coccobacillary. Colonies similar to but smaller than those of *P. anatis.* Nonhemolytic. No V-factor requirement. Acid is produced from D-mannitol and lactose; tests for ornithine decarboxylation, indole formation, urease activity, acid from L-arabinose, D-xylose, raffinose, trehalose, maltose, and D-sorbitol are negative. Strains of the species are found in the respiratory tracts of apparently healthy chickens. The species belongs to 16S rRNA cluster 19. The molecular weight of genomic DNA ranges from 1.7–1.9 × 10^9.

The mol% G + C of the DNA is: 43.9–45.3 (T_m).

Type strain: ATCC 43328, NCTC 11411.

GenBank accession number (16S rRNA): M75053.

8. **Pasteurella stomatis** Mutters, Ihm, Pohl, Frederiksen and Mannheim 1985a, 320[VP]

sto.ma' tis. Gr. gen. n. *stoma* throat, of the throat.

Cells are coccoid to rod shaped with bipolar staining ends in the Gram stain. On blood containing solid media small colonies of about 1 mm in diameter with grayish or semitranslucent appearance are formed. Nonhemolytic. Optimal growth temperature is 36°C. Strains fulfill the general criteria of the genus *Pasteurella sensu stricto.* Additionally they are V-factor independent, urease negative, and do not decarboxylate ornithine. No acid is produced from L-arabinose, D-xylose, raffinose, lactose, maltose, D-mannitol, D-sorbitol, or dulcitol. Indole positive. Occurs in the oral cavity or respiratory tract of dogs and cats. The species belongs to 16S rRNA cluster 12. The molecular weight of genomic DNA ranges from 1.5–1.6 × 10^9.

The mol% G + C of the DNA is: 40.4–43.5 (T_m).

Type strain: ATCC 43327, NCTC 11623.

GenBank accession number (16S rRNA): M75050.

9. **Pasteurella volantium** Mutters, Piechulla, Hinz and Mannheim 1985b, 9[VP]

vo.lan' ti.um. L. fem. gen. pl. n. *volantium* from fowl.

Cells coccoid. Occur singly or in short chains. Mesophilic, facultatively aerobic, and V-factor dependent. Nonhemolytic. On chocolate agar, colonies are smooth, convex, and may produce yellowish pigments. Phenotypic features are similar to *P. avium*, but acid production from maltose and D-mannitol is positive. Some strains decarboxylate ornithine, some strains produce acid from D-sorbitol. Strains are isolated from the wattles of domestic fowl, one strain has been isolated from human tongue (Kilian, 1976). The species belongs to 16S rRNA cluster 18. The molecular weight of genomic DNA ranges from 1.5–1.9 × 10^9.

The mol% G + C of the DNA is: 44–45 (T_m).

Type strain: ATCC 14385, NCTC 3438.

GenBank accession number (16S rRNA): M75070.

Other Organisms

1. *Pasteurella* species A (Mutters, Piechulla, Hinz, and Mannheim 1985b)

Strains of the unnamed *Pasteurella* species A resemble a collection of heterogeneous strains formerly classified as *Haemophilus avium.* All strains have a V-factor requirement and produce acid from L-arabinose, but not from D-sorbitol; the ornithine decarboxylase test is negative. Strains are isolated from poultry and wild birds. The species belongs to 16S rRNA cluster 18. The molecular weight of genomic DNA ranges from 1.7–2.1 × 10^9.

The mol% G + C of the DNA is: 44–45.9 (T_m).

Deposited strain: IPDH 280, HIM 789-5.

GenBank accession number (16S rRNA): M75055.

2. *Pasteurella* species B (Mutters, Piechulla, Hinz and Mannheim 1985b)

Cells are coccobacillary to rod shaped. Colonies are similar to *P. canis* or *P. stomatis.* Nonhemolytic. No V-factor dependency. Indole formation and ornithine decarboxylase tests are positive. Acid is produced from trehalose, maltose, D-xylose, and dulcitol. Acid is not produced from L-arabinose, D-mannitol, or D-sorbitol. Test for urease is negative. Strains are isolated from different animal hosts, but also from human dog-bite wounds or cat scratches. The species belongs to 16S rRNA cluster 12. The molecular weight of genomic DNA is 1.9 × 10^9.

The mol% G + C of the DNA is: 38.9–40.0 (T_m).

Deposited strain: CCUG 19794, SSI P 683.

GenBank accession number (16S rRNA): M75052.

Species Incertae Sedis

1. **Pasteurella aerogenes** McAllister and Carter 1974, 920[AL]

a.e.ro' gen.es. Gr. masc. n. *aer* air; L. v. *genere* to produce; M.L. adj. *aerogenes* gas-producing.

The species was excluded from the genus *Pasteurella* by DNA–DNA hybridization (Mutters et al., 1985a) and 16S rRNA hybridization (De Ley et al., 1990). Original isolates obtained from pigs. The species belongs to 16S rRNA cluster 14. Other isolates associated with 16S rRNA cluster 5. The molecular weight of genomic DNA is 1.6–2.0 × 10^9.

The mol% G + C of the DNA is: 41.8 (T_m).

Type strain: ATCC 27883.

GenBank accession number (16S rRNA): M75048.

2. **Pasteurella bettyae** Sneath and Stevens 1990, 151[VP]

be' tty.ae. M.L. gen. n. *bettyae* of Betty, to commemorate Elizabeth “Betty” O. King.

The species resembles the former CDC group HB-5 and was excluded genetically as well as by DNA–DNA hybridization data from the genus *sensu stricto* as by its phenotypic features, i.e., negative reactions for oxidase, no acid from D-galactose, fructose, D-mannose, or sucrose. Strains are obtained from human Bartholin gland abscesses and human finger infections. The species belongs to 16S rRNA cluster 9.

The mol% G + C of the DNA is: not determined.

Type strain: ATCC 23273, NCTC 10535.

GenBank accession number (16S rRNA): L06088.

3. **Pasteurella caballi** Schlater, Brenner, Steigerwalt, Moss, Lambert and Packer 1990, 320[VP] (Effective publication: Schlater, Brenner, Steigerwalt, Moss, Lambert and Packer 1989, 2173.)
ca.ba′ lli. Gr. n. gen. *cabilli* from a horse.
Strains of this taxon are different from true members of the genus by their aerogenic capacity and their negative catalase reaction. Some strains produce acid from *meso*-inositol and from L-rhamnose. Isolates are obtained from respiratory and genital tract infections in horses and also from humans who have had contact with horses. Cases of wound infections (Bisgaard et al., 1991a) and a wound infection after horse bite (Escande et al. 1997) have been reported. The species belongs to16S rRNA cluster 9.
The mol% G + C of the DNA is: 41–42 (T_m).
Type strain: ATCC 49197.
GenBank accession number (16S rRNA): AF224291.

4. **Pasteurella granulomatis** Ribeiro, Carter, Frederiksen and Riet-Correa 1990, 105[VP] (Effective publication: Ribeiro, Carter, Frederiksen and Riet-Correa 1989, 1402.)
gran.nu.lo′ ma.tis. L. dim. n. *granulum* grain; Gr. suff. *oma* a swelling or tumor; M.L. gen. n. *granulomatis* of a granuloma.
The nonhemolytic species was transferred to the genus *Mannheimia* as *Mannheimia granulomatis* Angen, Mutters, Caugant, Olsen and Bisgaard 1999a (see chapter on *Mannheimia*).
The mol% G + C of the DNA is: 39.2 (T_m).
Type strain: 26, ATCC 49244.

5. **Pasteurella lymphangitidis** Sneath and Stevens 1990, 151[VP]
lymph.ang.iti′ d.is. M.L. gen. n. *lymphangitidis* pertaining to lymphangitis, inflammation of the lymph nodes.
DNA–DNA hybridization data exclude the former BL organisms isolated from lymphangitis in *Bos indicus* in Southern India from the genus *Pasteurella* (Mutters et al., 1985a). The biochemical characteristics of a negative oxidase reaction, lack of nitrate reduction, and no acid formation from D-galactose and D-mannose phenotypically exclude this group from the genus.
The mol% G + C of the DNA is: not determined.
Type strain: ATCC 49635, NCTC 10547.

6. **Pasteurella mairii** *corrig.* Sneath and Stevens 1990, 151[VP]
mai′ ri.i. M.L. gen. n. *mairii* of Mair, after Nicholas S. Mair, who isolated the organism.
DNA hybridization data showed only low degrees of relatedness with *Pasteurella sensu stricto* as well as with other selected *Pasteurella*-named species (Mutters et al., 1985a). Strains are isolated from abortion in pigs and from septicemia in piglets. The species belongs to 16S rRNA cluster 14.
The mol% G + C of the DNA is: not determined.
Type strain: ATCC 49633, NCTC 10699.
GenBank accession number (16S rRNA): AF024532.

7. **Pasteurella pneumotropica** Jawetz 1950, 179[AL]
pneu.mo.tro′ pi.ca Gr. n. *pneumon* lung; Latinized Gr. adj. *tropicus* tropic, circle, M.L. fem. adj. *pneumotropica* having an affinity for the lungs.
Based on the molecular data, the two biovars Jawetz and Heyl resemble two distinct species outside the genus *Pasteurella*. The former Henriksen biovar has been reclassified as *Pasteurella dagmatis*. Overall, the *P. pneumotropica* complex remains heterogeneous, containing several unclassified new species (Ryll et al., 1991). The species belongs to 16S rRNA cluster 15. The molecular weight of genomic DNA is 1.5–1.6×10^9.
The mol% G + C of the DNA is: 40.3–42.8 (T_m).
Type strain: ATCC 35149, NCTC 8141.
GenBank accession number (16S rRNA): M75083.

8. **Pasteurella testudinis** Snipes and Biberstein 1982, 209[VP]
tes.tu′ di.nis. L. n. *testudo* tortoise; L. gen. n. *testudinis* of the tortoise.
The species has been recovered from healthy Californian desert tortoises (*Gopherus agassizii*) and from tortoises with upper respiratory tract disease (Snipes and Biberstein, 1982; Snipes et al., 1995). The species belongs to 16S rRNA cluster 21. The molecular weight of genomic DNA is 1.6×10^9.
The mol% G + C of the DNA is: 46.8–47.4 (T_m).
Type strain: ATCC 33688, UCD 90-23-79n.
GenBank accession number (16S rRNA): L06090.

9. **Pasteurella trehalosi** Sneath and Stevens 1990, 152[VP]
tre.hal.osi. M.L. gen. n. *trehalosum* pertaining to the carbohydrate trehalose.
The species includes the biovar T of the former *Pasteurella haemolytica*. Genotypic investigations have shown that the trehalose-positive biovar does not belong to the genus *Pasteurella* (Mutters et al., 1985a; De Ley et al., 1990; Dewhirst et al., 1993). Hemolysis on sheep blood agar and lack of acid formation from D(+) galactose also excludes the species from *Pasteurella*. Although these strains show no close affiliation to the genus *Pasteurella*, they were recently named *Pasteurella trehalosi* (Sneath and Stevens, 1990). The species belongs to 16S rRNA cluster 10. (The type strain has not been sequenced.) The molecular weight of genomic DNA is 1.8×10^9.
The mol% G + C of the DNA is: 42.6 (T_m).
Type strain: S110, ATCC 29703, NCTC 10370.

Genus II. **Actinobacillus** *Brumpt 1910, 849*[AL]

Ingar Olsen and Kristian Møller

Ac.ti.no.ba.cil′ lus. Gr. n. *actis* a ray; L. dim. masc. n. *bacillus* a small staff or rod; M.L. masc. n. *Actinobacillus* ray bacillus or rod.

Cells, measuring $0.4 \pm 0.1 \times 1.0 \pm 0.4$ µm, are spherical, oval, or rod-shaped (Phillips, 1984). **Most often bacillary but sometimes interspersed with coccal elements that may lie at the pole of a larger form, producing the characteristic "Morse-code" form.** Cell forms up to 6 µm in length may appear when grown on media containing glucose or maltose. Cells are single or arranged in pairs or, more rarely, in chains. Endospores are not formed. Gram negative, but staining is irregular. Not acid fast.

India ink may demonstrate small amounts of extracellular slime in wet preparations. **Nonmotile.** Organisms are aerobic, microaerobic, facultatively anaerobic, or chemoorganotrophic, having both respiratory and fermentative types of metabolism. After growth for 24 h on blood agar, translucent colonies, usually 1–2 mm in diameter appear. Surface colonies have low viability and may die in 2–7 days. Growth may be very sticky upon primary cultivation, making it difficult to remove colonies completely from the agar surface. Optimum growth temperature is 37°C. Temperature range for growth is 25–42°C.

Glucose is fermented, with production of acid but not gas. Inulin is not fermented, and inositol is fermented by *A. rossii* and infrequently by *A. porcinus* (Sneath and Stevens, 1985; Møller and Kilian, 1990; Møller et al., 1996a). Only *A. indolicus* is indole positive. **Nitrate reduction is positive** or variable (variable in *A. porcinus* [Møller et al., 1996a] and in *A. seminis* [van Tonder, 1979]). Actinobacilli are parasitic or commensal in humans, sheep, cattle, horses, pigs, other mammals, and birds. They are often commensals in the alimentary and genital tract and respiratory mucosa but can also occur as pathogens and cause a variety of lesions.

Genus *Actinobacillus* belongs to the family *Pasteurellaceae*. Virtually complete 16S rRNA sequencing has shown that this family is located in the *Gammaproteobacteria* (Dewhirst et al., 1992). Families closely related to the *Pasteurellaceae* are the *Enterobacteriaceae*, *Vibrionaceae*, and *Aeromonadaceae*. More distant relatives within the *Gammaproteobacteria* are the *Pseudomonas fluorescens* complex, the *Moraxellaceae*, and the *Cardiobacteriaceae*. DNA–rRNA hybridization found that the members of the *Pasteurellaceae* are most closely related to members of the *Enterobacteriaceae*, the *Vibrionaceae*, the *Aeromonadaceae*, and the genus *Alteromonas* (De Ley et al., 1990).

When 16S rRNA sequences were determined for over 70 strains of species in the family *Pasteurellaceae*, the strains were found to fall in seven clusters (Dewhirst et al., 1992, 1993). The first cluster, which is split into three subclusters, includes *Haemophilus sensu stricto*. This cluster contains the type strains of *H. influenzae*, *H. aegyptius*, *H. aphrophilus*, *H. haemolyticus*, *H. paraphrophilus*, *H. segnis*, and *A. actinomycetemcomitans*. It also contains *H. aphrophilus* NCTC 7901 and *A. actinomycetemcomitans* FDC Y4, ATCC 29522, ATCC 29523, and ATCC 29524. Cluster 2, which splits into two subclusters, contains *P. mairii* CCUG 27189, Bisgaard taxon 6 CCUG 15568, and the type strains of *A. seminis* and *P. aerogenes*. Cluster 3, including the genus *Pasteurella sensu stricto*, contains the type strains of *P. multocida*, *P. anatis*, *P. avium*, *P. canis*, *P. dagmatis*, *P. gallinarum*, *P. langaa*, *P. stomatis*, *P. volantium*, *P. trehalosi*, *H. haemoglobinophilus*, *H. parasuis*, *H. paracuniculus*, *H. paragallinarum*, *"A. salpingitidis"*, and *A. capsulatus*. It also comprises Bisgaard taxa 2, 3, 7, and 13, *Pasteurella* species A CCUG 18782, *Pasteurella* species B CCUG 19974, *Haemophilus* taxon C CAPM 5111, *H. parasuis* type 5 Nagasaki, and *P. volantium* NCTC 4101. Four subclusters exist in Cluster 3. The species belonging to *Pasteurella sensu stricto* fall in three of the four disconnected clusters. Cluster 4 contains the genus *Actinobacillus sensu stricto*, which includes the type strains of *A. lignieresii*, *A. equuli*, *A. pleuropneumoniae*, *A. suis*, *A. ureae*, *A. hominis*, *H. parahaemolyticus*, *H. paraphrohaemolyticus*, *H. ducreyi*, and *M. haemolytica*. This cluster also comprises *Actinobacillus* species strain CCUG 19799 (Bisgaard Taxon 11), *A. suis* ATCC 15557, *Haemophilus* "minor group" strain 202, *P. bettyae*, and Bisgaard taxa 5, 8, and 9 (*A. arthritidis* and genomospecies 2). Cluster 4 falls in two subclusters. Each species in these subclusters branch slightly deeper than do those in the cluster above, giving no logical point at which to end the genus *Actinobacillus sensu stricto*. The type strains of *P. pneumotropica* and *A. muris* form a fifth group. The sixth group is constituted by the type strain of *H. parainfluenzae* and by *H. parainfluenzae* ATCC 29242. Two strains of Bisgaard Taxon 14 and the type strain of *P. testudinis* form a seventh cluster.

The mol% G + C of the DNA is: 35.5–46.9.

Type species: **Actinobacillus lignieresii** Brumpt 1910, 849.

FURTHER DESCRIPTIVE INFORMATION

Cell morphology Actinobacilli show marked pleomorphism. Bacillary forms predominate, but coccobacilli and longer filaments can also be seen. The latter can break up into short bacillary forms or granules, which may give an appearance of streptobacilli or streptococcal chains.

Capsules are produced by most species. Extracellular slime can be seen especially in *A. equuli* and *A. suis*.

Cell constituents

FATTY ACIDS Cellular fatty acid patterns of established and newly described taxa in the family *Pasteurellaceae*, as determined by capillary gas chromatography, have been found to be homogenous with minor variations (Mutters et al., 1993). In this case, discrimination of species or groups within the family could not be achieved. Separation from the *Neisseriaceae* and *Moraxella* was possible. All *Pasteurellaceae* strains investigated show proportions of >15% for unbranched tetradecanoic acid $C_{14:0}$, hexadecanoic acids $C_{16:1}$, and $C_{16:1\ cis\ 9}$, and moderate amounts of 3-hydroxy-dodecanoic acid $C_{12:0\ 3OH}$, tetradecanoic acid $C_{14:5}$, pentadecanoic acid $C_{15:0}$, octadecanoic acid $C_{18:0}$, eikosanoic acids $C_{20:0}$ and $C_{20:4\ cis\ 5,8,11}$. In contrast to this, however, Boot et al. (1999) have found that principal component analysis of fatty acid data obtained under standardized growth conditions may discriminate among *Pasteurellaceae* species.

By using a column with a nonpolar stationary phase, it is possible to analyze free fatty acids from bacterial cells directly in the gas chromatograph without derivatization (Brondz and Olsen, 1983; Brondz et al., 1983). While *A. actinomycetemcomitans* strains can be divided into three groups based on their free fatty acid content, *H. aphrophilus* is homogeneous. However, the distribution of bound cellular fatty acids from whole cells is not so specific as to allow discrimination between *A. actinomycetemcomitans* and *H. aphrophilus* (Calhoon et al., 1981; Jantzen et al., 1981; Brondz and Olsen, 1984b).

The lipid content of lipopolysaccharide (LPS) from *A. actinomycetemcomitans* constitutes 35.4%; in *H. aphrophilus* it is only 18.4% (Brondz and Olsen, 1989).

3-Hydroxytetradecanoic acid and tetradecanoic acid, which are the sole LPS acids, make up 21.1% and 14.3%, respectively, of fatty acids in *A. actinomycetemcomitans*, and 10.9% and 7.5% in *H. aphrophilus*. Variation in the lipid content of LPS acids may explain in part the difference in periodontopathogenic potential between *A. actinomycetemcomitans* and *H. aphrophilus*.

When fatty acids of isolated outer membrane vesicles in species of *Actinobacillus*, *Haemophilus*, and *Pasteurella* were analyzed by gas chromatography and the data treated with multivariate analysis, it was found that *A. actinomycetemcomitans* can be assigned to one group (class 1) and *H. influenzae* to another (class 2) (Olsen et al., 1995). *H. aphrophilus*, *H. paraphrophilus*, and *P. multocida* are distinct from these classes, with the exception of the type strain of *H. aphrophilus*, which falls in class 1 (borderline). The abundance of 3-OH fatty acids indicates that the outer membrane vesicles are rich in LPS. Multivariate analysis of fatty acid

data from such vesicles can distinguish two groups of *A. actinomycetemcomitans* (Brondz et al., 1995). One group contains strains ATCC 33384^T, ATCC 29522, SUNY 366, HK 435, and Q 1247; the other group comprises ATCC 29524, ATCC 29523, FDC 2112, FDC 511, and SUNY 489.

Phospholipids The distribution of phospholipids, as determined by thin layer chromatography, is uniform within the family *Pasteurellaceae* (Mutters et al., 1993). Phosphatidylethanolamine has been observed in major amounts, phosphatidylglycerine in smaller amounts, and lysophosphatidylethanolamine in only petty amounts.

Lipoquines The lipoquine content can be used to discriminate between groups within the family *Pasteurellaceae*, but it does not necessarily reflect the degree of genomic relatedness (Mutters et al., 1993). *Actinobacillus* exhibits high amounts of menaquinone-7 (MK-7) (30%) and demethylmenaquinone-7 (DMK-7) (54%). Representative strains of *Haemophilus* contains mostly DMK-6, with smaller amounts (~10% each) of MK-8 and DMK-7. A group consisting of *A. actinomycetemcomitans*, *H. aphrophilus*, *H. segnis*, and *P. bettyae* has a profile similar to that of *Haemophilus*, but does not contain MK-8. Another group comprising *M. haemolytica* and Bisgaard Taxon 3 has a lipoprotein pattern between those of *Actinobacillus* and *Haemophilus*, whereas the patterns of *"Histophilus"*, *"A. salpingitidis"*, and *A. rossii* are completely different.

Of 16 strains of members of the *Pasteurellaceae* studied by high-performance liquid chromatography, 12 have been found to produce menaquinones, mostly as minor components, in addition to demethylmenaquinones (Kroppenstedt and Mannheim, 1989). These organisms represent the genus *Actinobacillus*, the genus *Pasteurella sensu stricto*, the *Mannheimia haemolytica* complex, *H. paragallinarum*, *H. parasuis*, *H. aphrophilus*, *P. aerogenes*, and Bisgaard Taxon 14. *P. pneumotropica* biotype Jawetz, members of the genus *Haemophilus sensu stricto*, and *A. actinomycetemcomitans* do not contain menaquinones. The view that the family *Pasteurellaceae* can be differentiated from the *Enterobacteriaceae* and other fermenting Gram-negative bacteria by a lack of menaquinones therefore cannot be maintained.

Carbohydrates There is a common pattern of cellular sugars among all members of the family *Pasteurellaceae*, and characteristic carbohydrate profiles discriminate between groups, often to the species level (Mutters et al., 1993). The sugar patterns distinguish, for example, *P. stomatis* from Bisgaard's Taxon 16, mannose-positive *A. hominis* strains from *A. equuli*, and *A. actinomycetemcomitans* from *H. aphrophilus*, *H. segnis*, and intermediate strains. Sugar profiles, established by gas chromatography of whole cells after methanolysis and derivatization with trifluoroacetic acid anhydride have demonstrated that *H. aphrophilus* differs from *A. actinomycetemcomitans*, *A. ureae*, *H. paraphrophilus*, *H. influenzae* type b, *M. haemolytica*, and *P. multocida* by its lack of D-glycero-D-mannoheptose (Brondz and Olsen, 1984d, 1985a). Whole defatted cells, which are intermediates between whole cells and isolated cell membranes, give the same sugar profiles as whole cells, reaffirming that D-glycero-D-mannoheptose is present in *A. actinomycetemcomitans* and absent in *H. aphrophilus* (Brondz and Olsen, 1984a). Further, multivariate analysis of quantitative chemical and enzymatic characterization data has demonstrated that D-glycero-D-mannoheptose is a true chemotaxonomic marker for these organisms (Brondz et al., 1990). LPS is the primary source of D-glycero-D-mannoheptose in *A. actinomycetemcomitans* and *H. paraphrophilus* (Brondz and Olsen, 1984c, 1985b). Whereas *A. actinomycetemcomitans* LPS contains 7.8% D-glycero-D-mannoheptose and 11.3% L-glycero-D-mannoheptose, *H. aphrophilus* LPS contains 17.4% L-glycero-D-mannoheptose (Brondz and Olsen, 1989).

Proteins One-dimensional SDS-PAGE of whole cell proteins has been used to characterize 39 strains representing all biovars established within the taxa 2 and 3 complex of Bisgaard and 2 strains belonging to the avian *M. haemolytica*–*"A. salpingitidis"* complex (Bisgaard et al., 1993). There is no correlation between results obtained from protein profiling and those previously established by DNA–DNA hybridization. Comparison of phena defined by protein profiling with species/groups established by DNA–DNA hybridization, chemotyping, and biotyping has shown that the best correlation exists between DNA–DNA hybridization and biotyping.

Both one- and two-dimensional electrophoresis of cellular proteins separate *A. actinomycetemcomitans* and *H. aphrophilus* (Calhoon et al., 1981; Jellum et al., 1984). The high resolution of the 2-D electrophoresis distinguishes strains within species, in contrast to 1-D electrophoresis. The 2-D whole-cell protein profiles of *A. actinomycetemcomitans*, *A. ureae*, *H. paraphrophilus*, *H. aphrophilus*, *H. influenzae*, *P. multocida*, and *M. haemolytica* have also been compared (Olsen et al., 1987). The protein patterns of the genera *Actinobacillus*, *Haemophilus*, and *Pasteurella* are quite distinct. *A. actinomycetemcomitans* can easily be distinguished from the other species tested, including *A. ureae*, *H. aphrophilus*, *H. paraphrophilus*, and *M. haemolytica*. The protein patterns of *P. multocida* and *M. haemolytica* also differ. However, it is difficult to distinguish strains of *H. paraphrophilus* and *H. aphrophilus*.

When outer membrane proteins of *A. actinomycetemcomitans* and *H. aphrophilus* strains were compared by means of SDS-PAGE and immunoblots with rabbit antiserum, the most prominent feature was found to be the absence of a heat-modifiable protein in *H. aphrophilus* (Bolstad et al., 1990). Another study has demonstrated a remarkable degree of homology between the outer membrane proteins of *A. actinomycetemcomitans* and *H. aphrophilus* (DiRienzo and Spieler, 1983). In addition, the principal heat-modifiable outer membrane protein of *A. actinomycetemcomitans* shows N-terminal sequence homology and immunologic cross reactivity with the OmpA proteins of other Gram-negative bacteria (Wilson, 1991).

Polyamines Analysis of polyamines is a promising method for discriminating members of the family *Pasteurellaceae* (Busse et al., 1997). Members of the genus *Actinobacillus sensu stricto* contain 1,3-diaminopropane as the predominant compound. In addition, in most of the species of the genus *Haemophilus*, 1,3-diaminopropane is the major substance. In contrast, however, "*H. intermedius* subsp. *gazogenes*" and *H. parainfluenzae* contain high levels of 1,3-diaminopropane, cadaverine, and putrescine. *H. parainfluenzae* is phylogenetically only distantly related to the type species of the genus *Haemophilus* (Dewhirst et al., 1993). The phylogenetic diversity of *Pasteurella* is also to some extent reflected by different polyamine patterns.

Enzymes Multivariate analysis of data (API-ZYM micromethod) from 19 enzyme activities in the outer membrane vesicles/fragments from clinically important species of the *Actinobacillus*–*Haemophilus*–*Pasteurella* group has enabled distinction among *A. actinomycetemcomitans*, *H. aphrophilus*, and *H. paraphrophilus* (Myhrvold et al., 1992). *A. actinomycetemcomitans* is divided

into two strain groups (classes). *A. lignieresii* falls outside or on the borderline of the *A. actinomycetemcomitans* class. *A. ureae*, *H. influenzae*, *H. parainfluenzae*, *M. haemolytica*, and *P. multocida* appear outside the *A. actinomycetemcomitans*, *H. aphrophilus*, and *H. paraphrophilus* classes. The API-ZYM method also distinguishes whole cells of *A. actinomycetemcomitans*, *A. lignieresii*, and *H. aphrophilus* (Slots, 1981).

The genetic diversity of 52 field isolates, mainly from Australia, and 15 reference strains of *A. pleuropneumoniae* has been examined with multilocus enzyme electrophoresis (MEE) (Hampson et al., 1993), and 33 electrophoretic types (ETs), with a mean genetic diversity per locus of 0.312, were found. Australian strains of serovars 1, 2, 5, and 7 belong to the same clonal lines as strains of these serovars from other countries. Distinct clones of serovars 3, 7, 11, and 12 are also detected. The type strains of serovars 1, 9, and 11 are placed in the same ET, and strains of *A. pleuropneumoniae* biovar 2 are closely related to biovar 1 strains.

MEE has also been used for clonal analysis of the *A. pleuropneumoniae* population in a geographically restricted Danish area (Møller et al., 1992). Sixty-six percent of 250 isolates from lungs of pigs with pleuropneumonia and from tonsils of apparently healthy pigs at slaughter belong to three ETs, out of a total of 37 ETs detected. While five biotype 2 isolates constitute a separate ET closely related to biotype 1 isolates, the type strain of the species constitutes its own ET, with a genetic distance of 0.30 from its nearest neighbor.

Genetic relationships among isolates assigned to *A. actinomycetemcomitans*, *H. aphrophilus*, and *H. paraphrophilus* can be examined based on electrophoretically demonstrable allelic variation in 14 structural genes coding for metabolic enzymes (Caugant et al., 1990). Among the 51 isolates that have been analyzed, 25 ETs are detected, with a genetic diversity of 0.753 per locus. Eleven ETs are seen with cluster analysis; these represent the genotypes of all 17 isolates assigned to *A. actinomycetemcomitans*. The remaining 14 ETs represent the genotypes of 34 isolates of *H. aphrophilus* and *H. paraphrophilus*. All strains of *H. aphrophilus* are closely related, except for ATCC 13252. Strains assigned to *H. paraphrophilus* include distantly related lineages, some of which are similar to *H. aphrophilus*. There is no significant overall genetic similarity between *A. actinomycetemcomitans* and the *Haemophilus* species examined.

Bacteriolysis The ability of ethylenediaminetetraacetic acid (EDTA) and hen egg white lysozyme to induce bacteriolysis has been tested in major clinical species of the *Actinobacillus–Haemophilus–Pasteurella* group (Olsen and Brondz, 1985). *A. actinomycetemcomitans* lyses more easily than does *H. aphrophilus*. The former can be divided into two strain groups according to lysis patterns, while *H. aphrophilus* is homogenous. In one group of *A. actinomycetemcomitans* (group I), EDTA has a considerable lytic effect, which is not increased by supplementation with lysozyme. In the other group of *A. actinomycetemcomitans* (group II), the lytic effect of EDTA is much less, but lysozyme has a considerable supplementary lytic effect. Maximal lysis of *A. actinomycetemcomitans* (ATCC 29522) occurs at pH 8.0 in the presence of EDTA and at pH 7.6 with EDTA–lysozyme. In *H. aphrophilus* (ATCC 33389^{T}) maximal lysis occurs at pH 9.0 with EDTA and at pH 9.2 with EDTA–lysozyme. When *H. influenzae*, *H. paraphrophilus*, *P. multocida*, *M. haemolytica*, and *A. ureae* were similarly tested, the group I strains of *A. actinomycetemcomitans* were found to be the most rapidly lysed by EDTA. *H. paraphrophilus* is the least sensitive of the Gram-negative organisms examined, but it is less resistant than *Micrococcus luteus*. The latter organism is the most sensitive to lysozyme, followed by *A. ureae* and the group II strains of *A. actinomycetemcomitans*. The group I strains of *A. actinomycetemcomitans*, *H. paraphrophilus*, and *M. haemolytica* are the least sensitive.

Multivariate analysis of 41 quantitative variables, including data from lysis kinetics after exposure to both EDTA and EDTA–lysozyme, cell sugar and fatty acid contents, methylene blue reduction, and API ZYM enzymatic assessment of whole cells and outer membrane vesicles/fragments, divides *A. actinomycetemcomitans* strains into two groups (Brondz and Olsen, 1993). One group contains ATCC 33384^{T}, ATCC 29522, FDC 2112, and FDC 2043; the other group comprises ATCC 29524, ATCC 29523, FDC 2097, FDC 511, and FDC Y4. Both groups are distinct from members of the genera *Haemophilus* and *Pasteurella*.

Cultural and biochemical characteristics The sticky properties of actinobacilli cultures when grown on nutrient agar or blood are marked with some species, but may be lost on subcultivation. The same stickiness may be revealed when cultures are grown in liquid media, especially those containing glucose. The increased viscosity is especially seen with *A. equuli* and to a lesser extent with *A. suis*. Stickiness can be demonstrated by drawing a strand of sticky material between the surface of the broth and the inoculating loop.

A few species exhibit hemolytic activity when cultured on blood agar. Evidence has been given for hemolytic *A. lignieresii* in horses (Samitz and Biberstein, 1991). A narrow zone of hemolysis may occasionally surround *A. minor* colonies when they are tested for the Christie Atkins and Munch–Petersen (CAMP) phenomenonon. Usually, *A. pleuropneumoniae* shows complete hemolysis on ovine and bovine blood agar, but occasionally, biovar 1 isolates may demonstrate incomplete or no hemolysis. However, the CAMP-reaction is always positive (Møller and Kilian, 1990). A zone of complete hemolysis always surrounds *A. suis* when it is cultured on ovine or bovine blood agar. In contrast, only partial hemolysis is observed when *A. suis* is grown on horse blood agar. Hemolytic *A. suis*-like organisms have been isolated from the oral cavity of horses (Bisgaard et al., 1984; Samitz and Biberstein, 1991).

Pigmented colonies are not produced, except in the case of *A. suis*, which reveals a creamy yellow color when its broth-grown cultures are centrifuged and the pellet resuspended in saline (Kim et al., 1976).

Usually, it takes 24–48 h for fermentation of carbohydrates and alcohols to occur, but some species or strains may need up to 7 days. Acid, but no gas is formed. Some substrates are fermented rather slowly. *A. succinogenes* accumulates high concentrations of succinic acid (Guettler et al., 1999).

A small number of *A. equuli* strains are gelatinase positive when tested by the gelatine plate method of Frazier (1926) (Frederiksen, 1973; Valleé et al., 1974).

Genome size/pulsed-field gel electrophoresis The genome size of the type strain (serotype 1) of *A. pleuropneumoniae*, as determined by pulsed-field gel electrophoresis (PFGE) of *Asc*I and *Apa*I digested chromosomal DNA, was 2404 ± 40 kb (Chevallier et al., 1998). The chromosome sizes for the reference strains of the other serotypes ranged between 2.3 and 2.4 Mb. Different PFGE patterns demonstrate heterogeneity of the chromosomal structure among different field strains of serotype 1, 5a, and 5b, while strains of serotype 9 show homogenous *Apa*I patterns. PFGE suggests that strains of *A. pleuropneumoniae* se-

rotype 2 obtained from Europe and North America are clonally related.

When *A. equuli* strains from 174 horses were examined by PFGE and restriction enzyme electrophoresis, a high degree of strain variability was found within each horse population (10 farms) and some variability over time was found between strains isolated from the same horse (Sternberg, 1998).

Valcarcel et al. (1997), using PFGE, found that the genome of *A. actinomycetemcomitans* contains a single chromosome of 2.3 Mb, estimated from the sum of restriction fragments generated with rare cutting endonucleases. Large plasmids with sizes ranging from 35–300 kb have been detected, and extrachromosomal elements constitute over 20% of the total genome in some strains.

16S rRNA data/phylogeny Phylogeny of the family *Pasteurellaceae* has been determined by comparison of 16S rRNA sequences (Dewhirst et al., 1992, 1993). The family has been divided into seven clusters, of which the fourth cluster contains the type strains of *A. lignieresii*, *A. equuli*, *A. pleuropneumoniae*, *A. suis*, *A. ureae*, *H. parahaemolyticus*, *H. parainfluenzae*, *H. paraphrohaemolyticus*, *H. ducreyi*, and *M. haemolytica*. This cluster also includes *Actinobacillus* sp. strain CCUG 19799 (Bisgaard Taxon 11), *A. suis* ATCC 15557, *H. ducreyi* ATCC 27722 and HD 3500, *Haemophilus* "minor group" strain 202, and *H. parainfluenzae* ATCC 29242. *A. hominis* is closely related to *Actinobacillus sensu stricto* species in Cluster 4A, while Bisgaard taxa 5, 8, 9 (*A. arthritidis* and genomospecies 2), and *P. bettyae* fall in Cluster 4B. The type strain of *A. actinomycetemcomitans* falls in the first cluster and also contains *A. actinomycetemcomitans* FDC Y4, ATCC 29522, ATCC 29523, and ATCC 29524, and *H. aphrophilus* NCTC 7901. The type strain of *A. seminis* is included in the second cluster, and the type strains of *A. capsulatus* and *"A. salpingitidis"* in the third cluster. *A. muris* is related to *P. pneumotropica*, and both are found in Cluster 5. The branching is extremely complex. For further information regarding these clusters, see genus definition at the head of this chapter.

The restriction pattern profiles of *Asc*I-, *Apa*I-, and *Nhe*I-digested chromosomes of different serotypes of *A. pleuropneumoniae* demonstrate a high degree of polymorphism (Chevallier et al., 1998). Analysis of the macrorestriction pattern polymorphism has provided a determination of phylogenetic relationships between the serotype reference strains. These relationships reflect to some extent groups of serotypes known to cross-react serologically.

Fussing et al. (1998b) has characterized and determined intraspecies relatedness of *A. pleuropneumoniae*, as well as its relationship to *A. lignieresii* and *A. suis*, by sequence analysis of the ribosomal operon. Amplification and sequence analysis of the 16S–23S rDNA ribosomal intergenic sequence (RIS) from the three species gives two RISs differing by about 100 bp. The larger RISs differ among the three species. A species-specific area has been found for *in situ* probe detection of *A. pleuropneumoniae*.

DNA–DNA hybridization DNA–DNA hybridization has been used extensively by the Mannheim group to determine the genetic relationships within and among genera of the family *Pasteurellaceae* (e.g., Mannheim and Pohl, 1980; Mannheim et al., 1980; Mannheim, 1983). DNA–DNA hybridization demonstrates the relative closeness of *Actinobacillus* and *Pasteurella* (Mannheim, 1983). Recently a micro-well format DNA hybridization method has been developed and validated on 23 strains belonging to *Actinobacillus* species, avian *[Pasteurella] haemolytica*-like bacteria and *Mannheimia* species (Christensen et al., 2000). Based on DNA homology studies, Escande et al. (1984) have suggested that the genus *Actinobacillus* be limited to *A. lignieresii*, *A. suis*, *A. capsulatus*, an unnamed equine *Actinobacillus* species (strain CCM 5500), and the generically misnamed *Pasteurella ureae*. *A. actinomycetemcomitans*, *"A. salpingitidis"*, and *A. seminis* have been suggested to not belong in the genus.

The degree of genetic relatedness of *A. pleuropneumoniae* to selected members of the family *Pasteurellaceae* has been determined by free solution DNA–DNA hybridization (Borr et al., 1991). Representative strains of all 12 serotypes of *A. pleuropneumoniae* form a homogenous group exhibiting 74–90% sequence homology with *A. pleuropneumoniae* serotype 1. All serotypes show a high degree of genetic relatedness to *A. lignieresii*. Little homology has been demonstrated between *A. pleuropneumoniae* strains and selected *Haemophilus* and *Pasteurella* species.

A. pleuropneumoniae serotype reference strains and 204 field strains representing all 12 serotypes and biovars 1 and 2 have been analyzed for the presence of a number of toxin genes by DNA–DNA hybridization with specific gene probes (Beck et al., 1994). The patterns of *apx* genes and those of the expressed Apx toxins in biovar 1 field strains are the same as the patterns in the corresponding serotype reference strain. Nearly all strains expressed their *apx* genes and produced the same Apx toxins as their serotype reference strain.

The DNA homology between serovars (1–13) of *M. haemolytica* and other species (*P. multocida* and actinobacilli) has been found to be low (Bingham et al., 1990), suggesting essentially no genetic relationship of *M. haemolytica* with the ATCC reference strains of *Pasteurella* or *Actinobacillus*.

"H. somnus" DNA shows 43%, 46%, and 58% homology with the DNA from *A. lignieresii*, *H. influenzae*, and *H. parainfluenzae*, respectively (Gonzales and Bingham, 1983).

Based on DNA relatedness Coykendall et al. (1983) have suggested that *A. actinomycetemcomitans* is distinct from *H. aphrophilus* and *H. paraphrophilus*. Furthermore, DNA–DNA hybridization has been used by Tønjum et al. (1990) to identify clinical isolates as *A. actinomycetemcomitans* and *H. aphrophilus*. The results obtained with hybridization are supported by interstrain-to-intrastrain genetic transformation ratios. Distinction between *A. actinomycetemcomitans* and *H. aphrophilus* is generally clear-cut with respect to both hybridization and genetic transformation. Distinction between these two species has also been obtained with DNA–DNA hybridization using total genomic DNA probes (Tønjum et al., 1989).

DNA–rRNA hybridization DNA–rRNA hybridization studies demonstrate at least seven rRNA branches in the family *Pasteurellaceae* (De Ley et al., 1990). The *A. actinomycetemcomitans*, *H. aphrophilus*, *H. ducreyi*, and *"Histophilus ovis"* rRNA branches are separate and quite remote from the three authentic genera of the family. DNA–rRNA hybridization with labeled probes is therefore an excellent method to decide whether an organism belongs to the family *Pasteurellaceae* or not.

When chromosomal DNA from *A. actinomycetemcomitans* is digested with the restriction endonucleases *Cla*I, *Bam*HI, *Bgl*II, or *Hin*dIII and hybridized to the rrnB ribosomal RNA operon of the *Escherichia coli* chromosome, isolates from the same individual and, belonging to the same serotype are found to be genetically identical, but those belonging to different serotypes are nonidentical (Saarela et al., 1993). Isolates of the same or different serotypes are genetically nonidentical in different individuals.

Typing systems

Biochemical typing The possibility of using biochemical differences among strains of a given serotype as epidemiological markers has been examined in *A. pleuropneumoniae*. Sirois and Higgins (1991) applied 38 biochemical and physiological tests to distinguish 67 strains belonging to serotype 1 and 5. Three fermentation tests have allowed the classification of serotype 1 strains into six phenotypic groups and serotype 5 strains into four of these groups. Groups II and III contain exclusively serotype 1 strains, whereas the majority of strains in groups I and IV belongs to serotype 1 and 5, respectively. The latter contains almost all the serotype 5 strains studied.

Serotyping Phillips (1967) has conducted serological and antigenic structure typing of *A. lignieresii*. Serological characterization of *A. pleuropneumoniae* in Australian pigs from 1993–1996 demonstrates that the dominant serovars are 12, 1, and 7 (Blackall et al., 1999a). In pigs from Quebec, serotype 1 is predominant, while serotype 5 is second in prevalence (Mittal et al., 1992). Both subtypes of serotype 5 (5a and 5b) are present in Quebec. Serotypes 3, 6, 7, 8, 10, and 12 have been isolated in small numbers, whereas serotypes 4, 9, and 11 are not present. Quantitation of the type- and group-specific antigens by the coagglutination test distinguishes serotype 1 and 9 strains from those of serotype 11 (Mittal et al., 1993).

Long-chain lipopolysaccharides have been used for the detection of antibodies in animals infected with *A. pleuropneumoniae* serotypes 4 and 7 (Gottschalk et al., 1997).

Using a monoclonal antibody-based polystyrene agglutination test, Dubreuil et al. (1996) have identified serotype 5a and 5b strains of *A. pleuropneumoniae*. Mittal et al. (1988b) have found serotype 6 strains of *A. pleuropneumoniae* to be antigenically closer to serotype 8 than to serotypes 3 or 5. A combination of serological tests, such as coagglutination followed by 2-mercaptoethanol tube agglutination, and immunodiffusion tests distinguish serotype 6 strains from those of other cross-reacting serotypes. Serotype-3 strains of *A. pleuropneumoniae* possess epitopes shared with almost all other serotypes (Mittal et al., 1988a).

Serotype-specific rabbit antisera against *A. actinomycetemcomitans* have been used to serotype 177 isolates of this organism from 136 periodontally healthy or diseased subjects by indirect immunofluorescence and/or immunodiffusion assays (Asikainen et al., 1991). Serotype b is dominant in subjects with periodontal disease, and serotype c is the most common serotype in healthy subjects. Most subjects are infected with only one serotype, and *A. actinomycetemcomitans* infections are relatively serotype-stable. Nonserotypeable *A. actinomycetemcomitans* isolates may originate from serotypeable isolates, especially those of serotype c (Paju et al., 1998).

Sensitized latex particles (SLP) for detection of capsular polysaccharides have been applied to the typing and diagnosis of *A. pleuropneumoniae* (Inzana, 1995). The SLP are agglutinated by all strains of the homologous serotype, but not by heterologous serotypes or strains of *A. suis*, *P. multocida*, or *H. parasuis*.

Restriction mapping Minor differences in the cleavage patterns of 17 serotype 7 strains of *A. pleuropneumoniae*, detectable by restriction endonuclease analysis (REA), enable grouping of these strains into seven profiles (Wards et al., 1998).

DNA fingerprinting has also been used to differentiate 12 reference strains, each representing one serotype, and 11 field strains of *A. pleuropneumoniae* belonging to serotype 9, which is the most frequent *Actinobacillus* species in the Czech Republic (Rychlik et al., 1994). Nine of the reference strains can be distinguished from each other and from serotypes 1, 9, and 11. A close relationship exists between the latter three. Among the 12 serotype 9 strains, four DNA types can be identified. REA is also powerful for typing and discerning genetic heterogeneity and homogeneity among *A. actinomycetemcomitans* strains (Han et al., 1991).

Genomic DNA fingerprinting by restriction-fragment-end-labeling classifies 31 strains of *A. actinomycetemcomitans* into 29 distinct types based on polymorphism (van Steenbergen et al., 1995). Serotype-specific fragments can be assigned for the three serotypes investigated.

Restriction fragment-length polymorphism (RFLP) has been used to study the epidemiology and pathogenesis of *A. actinomycetemcomitans* (DiRienzo and Slots, 1990). RFLP type B of *A. actinomycetemcomitans*, corresponding to reference strain JP2, seems to be particularly virulent, as indicated by the presence of this type in three subjects who converted from a healthy periodontal state to localized juvenile periodontitis.

Ribotyping Ribotyping is more efficient than biochemical fingerprinting in detecting differences between isolates of *A. equuli* from healthy and diseased horses (Sternberg and Brandstrom, 1999). There is a poor correlation between the methods. In *A. pleuropneumoniae*, ribotyping has been evaluated as an epidemiological tool and applied to study infections caused by this organism in Danish pig herds (Fussing et al., 1998a). This assessment was based on 13 reference strains and 106 epidemiologically unrelated field strains representing the nine serotypes of biotype 1 and serotype 14 of biotype 2. The enzymes *Cfo*I and *Hin*dII were used to provide ribotype patterns. Ribotyping of the reference strains resulted in 10 *Cfo*I types and 11 *Hin*dIII types. From the Danish herd strains, 17 different *Cfo*I ribotypes and 24 *Hin*dIII ribotypes were established. Combining *Hin*dIII- and *Cfo*I-ribotyping divides the herd strains into 26 different types.

The genomic relationships among 112 *A. pleuropneumoniae* serotype 2 strains collected throughout Europe and North America have been examined by Fussing (1998). *Hin*dIII ribotyping of the strains produced five ribotypes with high similarity. Sequence analysis of the ribosomal intergenic region of strains representing each ribotype and each country demonstrates no differences. PFGE patterns of strains representing all countries show high similarity, suggesting that strains of *A. pleuropneumoniae* serotype 2 are clonal.

Six different typing methods have been compared for *A. actinomycetemcomitans* (van Steenbergen et al., 1994). Ribotyping provides unequivocal distinction among different strains, as compared to restriction endonuclease results. Serotyping, biotyping, and SDS-PAGE patterns of outer membrane proteins are reproducible, but have a low discriminatory potential. Ribotyping shows intrafamilial similarity among *A. actinomycetemcomitans* isolates (Alaluusua et al., 1993) and supports separation of *A. actinomycetemcomitans* from *H. aphrophilus* and *H. paraphrophilus* (Sedlácek et al., 1993).

PCR-ribotyping, repetitive extragenic palindromic element (REP)-based PCR and enterobacterial repetitive intergenic consensus (ERIC)-based PCR have been used for strain differentiation in epidemiological studies of *A. seminis* (Appuhamy et al., 1998). PCR-ribotyping gives the simplest pattern and is useful in differentiating *A. seminis* strains and distinguishing this species from related species.

REA of PCR-amplified 16S rRNA genes *A. actinomycetemcomitans*, *H. aphrophilus*, and *H. paraphrophilus* can be rapidly distinguished by REA of PCR-amplified 16S rRNA genes (Riggio and Lennon, 1997).

Multiplex PCR A multiplex PCR assay has been developed for detection of *A. pleuropneumoniae* and identification of serotype 5 isolates (Lo et al., 1998). DNA sequences specific to the conserved export and serotype-specific biosynthesis regions of the capsular polysaccharide of *A. pleuropneumoniae* serotype 5 are applied as primers to amplify 0.7 and 1.1 kb DNA fragments, respectively. The multiplex PCR assay rapidly detects *A. pleuropneumoniae* and distinguishes serotype 5 strains from other serotypes.

AP-PCR Hennessy et al. (1993) have recommended the use of M13 and T3–T7 oligodeoxynucleotide primers for diagnostic and epidemiological identification of *A. pleuropneumoniae* by arbitrarily primed (AP) PCR techniques. In *A. actinomycetemcomitans*, the isolates of a given AP-PCR genotype usually belong to the same serotype (Asikainen et al., 1995).

Toxin typing A PCR method that has been developed for toxin typing of *A. pleuropneumoniae* is useful in differentiating strains for diagnostics and epidemiology and in detecting serotypes with atypical toxin patterns (Frey et al., 1995, 1996).

Antigenic structure Actinobacilli have a complex antigenic structure. Heat-stable somatic antigens and heat-labile surface antigens have been demonstrated in *A. lignieresii*, *A. equuli*, *A. pleuropneumoniae*, and *A. suis* (Phillips, 1967; Mráz, 1969a; Kim, 1976; Nielsen, 1990). Species may be divided into different antigenic types. Six antigenic types, 1–6, have been detected in *A. lignieresii*, with 2 subtypes, 1a and 4c, based on heat-stable antigens (Phillips, 1967). Most cattle strains in the UK belong to type 1 and most sheep strains to types 2, 3, and 4. Diverging distributions may be found in other geographic areas. In Japan, type 3 is found in cattle and the predominant type is 5 (Nakazawa et al., 1979). In *A. lignieresii* heat-labile antigens associated with extracellular slime may cause cross reaction in agglutinating tests if unheated suspensions of the different antigenic types are used. In *A. equuli*, both heat-labile and heat-stabile antigens have been demonstrated, and a number of antigenic groups have been detected. Mráz (1968) has demonstrated the presence of antigenic groups in this organism, and Kim (1976) has distinguished 28 groups based on heat-stable O antigens. There is no evidence of host specificity among groups.

In *A. pleuropneumoniae*, 14 serovars have been recognized based on soluble surface antigens composed of capsular polysaccharides and lipopolysaccharides (in addition serovars 1 and 5 can be subdivided into 1a, 1b and 5a, 5b, respectively) (Jolie et al., 1994; Nielsen et al., 1997b).

A. rossii shows serological cross-reactions with *A. lignieresii*, *A. equuli*, *A. suis*, *A. seminis*, and *M. haemolytica* (Ross et al., 1972).

No detailed study has been made of the antigens of *A. suis*, but there is a marked uniformity in the antigenic structure of 16 strains taken from Britain, Denmark, Germany, and the United States (Kim et al., 1976).

There are antigenic cross relationships between *A. suis*, *A. lignieresii*, and *A. equuli* (Haupt, 1934; Valleé et al., 1963, 1974; Wetmore et al., 1963; Bouley, 1966; Kim, 1976). Furthermore, actinobacilli and pasteurellae share antigens (Mráz, 1969a, 1977; Ross et al., 1972).

Pulverer and Ko (1972) have found 6 heat-stable agglutinating antigens in *A. actinomycetemcomitans* and have established 24 agglutinating patterns among 100 strains. King and Tatum (1962) have detected 3 precipitating antigens distributed singly among different strains. This has been confirmed by Zambon et al. (1983), who named the 3 serotypes a, b, and c. Later, serotypes d and e were added (Saarela et al., 1992; Gmür et al., 1993). Zambon et al. (1983) have found that *A. actinomycetemcomitans* cross-reacts with *H. aphrophilus*.

Tube agglutination with somatic antigens reveals 5 serotypes in *"A. salpingitidis"* that differ from other actinobacilli and closely related pasteurellae (Mráz et al., 1976). Presumed existence of a thermostable envelope antigen has been found by gel precipitation, according to Ouchterlony (1968). Its low specificity demonstrates the resemblance of all species within the genus, as well as in the group of *Actinobacillus–Pasteurella* (Mráz et al., 1976).

Pathogenicity and sources Actinobacilli have low pathogenicity in experimental animals. Efforts to produce specific lesions with *A. lignieresii* in laboratory animals have usually failed. Chick and mice embryos may be more susceptible than guinea pigs and rabbits (Mráz, 1969a, b). Mice that are injected intraperitoneally and chick embryos affected by injection into the allantoic cavity usually die (Holmes, 1998). *A. equuli* is not pathogenic in mice, and *A. equuli* and *A. suis* are not detrimental to guinea pigs and rabbits. *A. pleuropneumoniae* causes infection in mice by the intraperitoneal and intranasal route, and *A. suis* infects mice by the intraperitoneal route. *A. ureae* is slightly pathogenic for guinea pigs, mice, and rabbits (Henriksen and Jyssum, 1961).

Actinobacilli were first found associated with cattle, but have since been isolated from other animals and humans (Peel et al., 1991). In domestic animals, they occur both as pathogens and commensals. As commensals, actinobacilli are present in the alimentary, respiratory, and genital tracts of normal animals. *A. lignieresii* has a commensal role in the mouth and rumen of healthy cattle and sheep (Phillips, 1961, 1964; Bisgaard et al., 1986). Invasion and establishment within tissue usually promote the transition from commensalism to pathogenicity. This implies that actinobacilli often operate as opportunists. A number of human infections are the result of animal bites. Actinobacilli usually cause sporadic disease, but sometimes a group of animals is affected by a common trigger factor.

A. lignieresii produces actinobacillosis in cattle and sheep. Several predisposing factors exist, and there is considerable variation in pathogenicity between strains, some of which do not cause disease at all (Magnusson, 1928). Lignières and Spitz (1902) isolated an organism from actinomycotic lesions of soft tissue in cattle that they named "l' actinobacille" due to the nature of the lesion, described as actinobacillosis. In cattle, chronic granulomatous lesions are found most frequently on the tongue ("wooden tongue") and in other soft tissues of the head and upper alimentary tract. Subcutaneous injection into cattle may produce an abscess similar to that occurring naturally. Granules consisting of rods surrounded by clubs are present in the pus. Lymph nodes in the region are invariably affected. Christiansen (1917) was the first to describe the organism in sheep as *"Bacterium purifaciens"*. Tunnicliff (1941) concluded that it was similar to the organism isolated from cattle. Skin, lungs, testes, and mammary glands are the sites most commonly affected in sheep.

In addition to infections in cattle and sheep, *A. lignieresii* has been isolated from an epidural abscess (Chladeck and Ruth, 1976), an intramandibular phlegmon (Zaharija et al., 1979), and an enlarged tongue (Baum et al., 1984) of horses. *A. lignieresii* infections in humans bitten by horses and sheep have been re-

ported (Dibb et al., 1981; Clark et al., 1984; Peel et al., 1991; Benaoudia et al., 1994). *A. arthritidis* has been isolated from the cavum oris of apparently healthy horses, as well as from joints of horses with arthritis, and from horses and foals with septecemia (Christensen et al., 2002a).

A. suis is an opportunistic pathogen of swine of all ages and has been isolated from healthy pigs (Cutlip et al., 1972; van Ostaaijen et al., 1997). Generally, *A. suis* is associated with septicemia and death in suckling and newly weaned piglets. However, septicemia in mature swine has also been reported (Miniats et al., 1989; Yaeger, 1996). Localized infections, such as endocarditis, polyarthritis, subcutaneous abscesses, and pneumonia, have also been observed (Zimmermann, 1964; Mair et al., 1974). Human infection has been reported as the result of a pig bite (Escande et al., 1996). It is likely that equine strains of organisms, described as *A. suis* or hemolytic variants of *A. equuli* may constitute a separate group of organisms, provisionally designated taxon 11 (Bisgaard et al., 1984).

A. equuli causes septicemia, often in association with nephritis, arthritis, pneumonia, pleuritis, or enteritis in young foals, a condition referred to as "sleepy foal disease" or "joint ill." Adult horses may suffer from arthritis, pneumonia, endocarditis, pericarditis, nephritis, meningitis, and metritis. Abortion may occur in pregnant animals. Golland et al. (1994) have described 15 cases of peritonitis in horses. In piglets that are a few days old, *A. equuli* may cause septicemia (Pedersen, 1977), while older pigs may suffer from arthritis, endocarditis, osteomyelitis, nephritis, and pneumonia. *A. equuli* occurs as a commensal in the equine intestinal tract and mouth. It has not been isolated from normal swine. An *A. equuli*-like bacterium has been isolated from an infected horse bite wound in a human being (Peel et al., 1991).

A. hominis was originally isolated from patients with chronic lung disease, but it is also an etiologic agent of septicemia in hepatic failure (Wüst et al., 1991) and pleural empyema (Friis-Møller and Kharazmi, 1988). It has not been isolated from animals.

A. ureae has been isolated from the human respiratory tract, sputum, and cerebrospinal fluid (Henriksen and Jyssum, 1961; Jones, 1962; Verhaegen et al., 1988). In 11 cases, it has been the primary pathogen of meningitis (Kingsland and Guss, 1995). It has also been isolated from bone marrow infection (Avlami et al., 1997), chronic bronchitis, pneumonia, sepsis, and peritonitis (Kingsland and Guss, 1995). Strains vary in virulence and have no animal host (Kolyvas et al., 1978).

A. pleuropneumoniae is the etiologic agent of a highly contagious and often fatal acute or chronic pleuropneumonia in swine. As opposed to other actinobacilli, *A. pleuropneumoniae* is a primary pathogen. Pigs that survive the infection often become subclinical carriers. *A. pleuropneumoniae* has been isolated from 42% of tonsils from 303 chronically infected slaughterhouse swine (Møller and Kilian, 1990). It is rarely recovered from the nasal cavity and the lungs. Although isolates of all serovars may cause disease, significant differences in their pathogenic potential have been reported (Rosendal et al., 1985; Jacobsen et al., 1996). Several virulence factors have been described, including capsules, lipopolysaccharides, outer membrane proteins, transferrin binding proteins, and Apx toxins (Haesebrouck et al., 1997). The capsule consists of derivatized repeating oligosaccharides. The DNA region involved in the export of capsular polysaccharide by *A. pleuropneumoniae* serovar 5a has been characterized (Ward and Inzana, 1997). Among the different bio- and serovars of *A. pleuropneumoniae*, three exotoxins have been described: ApxI and ApxII, which are hemolytic, and ApxIII, which is non-hemolytic (Frey et al., 1993; Jansen, 1994). They are toxic to porcine alveolar macrophages and neutrophiles and belong to the pore-forming RTX toxins, which are widely spread among pathogenic Gram-negative bacteria, including the *Pasteurellaceae* family (Frey et al., 1994). *A. lignieresii*, *A. equuli*, and *A. suis* also possess RTX cytolysin genes, and *A. suis* produces proteins similar to ApxI and ApxII (Burrows and Lo, 1992; Kamp et al., 1994).

A. scotiae has been isolated from porpoises (*Phocoena phocoena*) stranded on the Scottish coastline (Foster et al., 1998). One strain ($M2000/95/1^T$) was recovered from the brain, lung, spleen, liver, mesenteric lymph node, blood, and small intestine of one animal that died of septicemia.

A. delphinicola has been isolated from harbor porpoises, a Sowerby's beaked whale, and a striped dolphin (Foster et al., 1996). The pathological significance of this organism for the sea mammal species is not clear.

A. indolicus, *A. minor*, and *A. porcinus* are isolated from the upper respiratory tracts of pigs, where they constitute part of the residing mucosal flora (Møller et al., 1996a). They are not pathogenic to pigs, as indicated by inoculation experiments (Rosendal et al., 1985; Brandreth and Smith, 1986).

A. rossii has been isolated from the vaginas of postparturient sows and aborted piglets (Ross et al., 1972; Sneath and Stevens, 1990).

A. capsulatus has been described in rabbits, where it acts as an agent of arthritis (Arseculeratne, 1962; Phillips, 1984), in hamsters (Krause et al., 1989), and in the lungs, livers, and/or spleen tissue of snowshoe hares (Zarnke and Schlater, 1988). Isolation of *A. capsulatus* in pure culture from animals with fatal infections indicates that it may act as a primary pathogen. Inoculation experiments have shown that domestic rabbits injected intravenously with *A. capsulatus* develop lung and liver lesions similar to those observed in naturally infected hares (Arseculeratne, 1962).

A. muris has been isolated from the pharyngeal flora of healthy white laboratory mice and from uteri and vaginas of apparently healthy mice (Bisgaard, 1986).

A. succinogenes has been cultured from the bovine rumen (Guettler et al., 1999). It produces succinate-pathway enzymes in much higher amounts than do other succinic-producing bacteria (van der Werf et al., 1997). Its general properties are suggestive of a microorganism adapted to a symbiotic role in the rumen.

A. seminis has been associated with epididymitis and orchitis in rams (Baynes and Simmons, 1960, 1968; van Tonder, 1973, 1979; Erasmus et al., 1982; Sponenberg et al., 1983; De Wet and Erasmus, 1984), ovine contagious epididymitis (Ajai et al., 1980; Burgess, 1982), mastitis in ewes (Alsenosy and Dennis, 1985), polyarthritis and posthitis in sheep (Watt et al., 1970) and abortion in sheep (Foster et al., 1999).

A. actinomycetemcomitans is indigenous to humans. The pathogenicity of *A. actinomycetemcomitans* in humans has been doubted, since it is detected with actinomycetes in more than 30% of actinomycotic lesions (Heinrich and Pulverer, 1959b). However, recent evidence implicates *A. actinomycetemcomitans* in the etiology of destructive periodontal diseases in man (e.g., Zambon, 1985; Zambon et al., 1988; Haffajee and Socransky, 1994). It has also been isolated from abscesses (abdominal [Garner, 1979], brain [Martin et al., 1967; Garner, 1979], facial [Page and King, 1966], hand [Mauff et al., 1983], mediastinal [Garland and Prichard, 1983], and thyroid [Burgher et al., 1973]), as well as from actinomycosis (Colebrook, 1920), endarteritis (Symbas et

al., 1967), endocarditis (Mitchell and Gillespie, 1964), meningitis (Page and King, 1966), pneumonia (Meyers et al., 1971), septicemia (Page and King, 1966), urinary tract infection (Townsend and Gillenwater, 1969), and vertebral osteomyelitis (Muhle et al., 1979).

"A. salpingitidis" is isolated from the respiratory tract and oviduct of clinically healthy domestic fowl, from salpingo-peritonitis in hens, and from organs of dead chicks and young turkeys (Mráz et al., 1976). It is a commensal in the respiratory tract and oviduct of domestic fowl. Independent infections arise on the basis of previous weakening; the others are of mixed or secondary character (e.g., mycoplasmosis, organ tuberculosis, leukocytosis, parasitic invasion). *"A. salpingitidis"* is pathogenic for 5-day-old chicks and eventually for white mice. Guinea pigs and rabbits are not susceptible.

Enrichment and Isolation Procedures

Enriched media (blood agar or serum agar) used for the isolation of pathogens from animal tissues can also be used for the primary isolation of actinobacilli from tissues. For the V-factor-dependent actinobacilli (*A. indolicus*, *A. minor*, *A. pleuropneumoniae* biovar 1, and *A. porcinus*), enriched media should include NAD, or a nurse-strain should be used as described in the *Haemophilus* chapter. For primary isolation of *A. pleuropneumoniae* from pleuropneumonic lungs, enriched[1] bovine blood agar plates cross-streaked with a β-hemolytic *Staphylococcus aureus* strain will support the growth and enhance the hemolytic pattern. Media suitable for serotyping and genetic characterization of *A. pleuropneumoniae* are chocolate agar (see Genus *Haemophilus*, this edition), PPLO agar (Nicolet, 1971), and brain heart infusion broth supplemented with 10 mg/l NAD (Møller et al., 1996a).

Selective media may prevent overgrowth of actinobacilli when they are present in mixed cultures. Such media have been used to recover *A. lignieresii* from the mouths of normal cattle (Till and Palmer, 1960) and from the rumens of normal cattle and sheep (Phillips, 1961, 1964), *A. indolicus*, *A. minor*, and *A. porcinus* from the upper respiratory tract (Møller and Kilian, 1990), and *A. actinomycetemcomitans* from the periodontal pocket (Slots, 1982b). Selective and indicator media for isolation of *A. pleuropneumoniae* from the pharyngeal tonsils of chronically infected swine have been described (Møller et al., 1993; Sidibé et al., 1993; Jacobsen and Nielsen, 1995).

Gram and Ahrens (1998) have developed a PCR method for specific detection of *A. pleuropneumoniae*. When used to detect *A. pleuropneumoniae* from tonsils of carrier pigs, the PCR method, combined with cultivation, shows a high sensitivity as compared to cultivation alone. The PCR amplifies the outer membrane lipoprotein (*oml*A) gene. A multiplex PCR for specific detection of *A. pleuropneumoniae* serovar 5 has been developed by Lo et al. (1998). DNA sequences specific to the conserved export and serotype-specific biosynthesis regions of the capsular polysaccharide of *A. pleuropneumoniae* serovar 5 are used as primers. Frey et al. (1995) have developed a PCR method that allows determination of the activator, structural, and secretion genes of the three toxins ApxI, ApxII, and ApxIII in *A. pleuropneumoniae*. The profile of the individual genes in the three Apx operons is constant for a given serotype. Despite the high similarity between 16S rDNA from *A. pleuropneumoniae* and *A. lignieresii*—with differences in only three positions—a species-specific oligonucleotide for *in situ* detection of *A. pleuropneumoniae* has been constructed (Fussing et al., 1998b).

Maintenance Procedures

Most strains die on blood agar or serum agar within 4 d (Phillips, 1984). Cultures grown in Robertson's cooked medium may be stored for up to 4 weeks, and when lyophilized in sterile rabbit serum, 20% peptone solution, or skim milk, for up to 20 years. When heavy suspensions of cultures are grown on nutrient agar, blood agar, chocolate agar, or PPLO agar and washed off in the solutions described for lyophilization, they may be stored at −70°C for up to 2 years without loss of viability.

Procedures for Testing Special Characters

V-factor requirement V-factor requirement is demonstrated on agar medium lacking the V factor by cross-inoculation of the plate with a nurse strain (e.g., *Staphylococcus* or *Pseudomonas*) or application of a V-factor-impregnated paper disk (Genus *Haemophilus*, this edition).

Fermentation of carbohydrates Fermentation of carbohydrates for the V-factor-dependent species can be examined in phenol red broth base (Difco) supplemented with 1% of the respective carbohydrates and 10 μg/ml NAD (Genus *Haemophilus*, this edition).

Micromethods for examination of V-factor-dependent actinobacilli The micromethods do not require growth and are recommended for the detection of indole production, urease, ornithine and lysine decarboxylases, arginine dihydrolase, and glycosidase activities (Genus *Haemophilus*, this edition).

Differentiation of the genus *Actinobacillus* from other genera

Actinobacilli are distinguished from enterobacteria by their smaller genome, (e.g., *A. pleuropneumoniae*, with 2404 ± 40 kb) (Chevallier et al., 1998), obligatory parasitism, and absence of motility. They differ from the vibrios by their smaller genome, absence of flagella, and other phenotypic properties.

Complex genomic relationships have been shown by DNA–DNA hybridization to exist between members of the genera of the family *Pasteurellaceae* (Pohl, 1979). The phenotypic distinction of *Actinobacillus* and *Pasteurella* is difficult to determine with the existing composition of the genera (Sneath and Stevens, 1985). DNA–DNA hybridization studies show that the traditional genus names in *Pasteurellaceae* can be kept only if the genera are restricted to entities clustering at or above 50% DNA binding level with the type species of the genera (Mutters et al., 1985a). This is a practical choice, since there is no consensus as to which level genera should be defined within different families. rRNA–DNA hybridization identifies seven rRNA branches, in addition to numerous unclustered taxa within the family *Pasteurellaceae* (De Ley et al., 1990). 16S rRNA sequencing of 70 strains representing different taxa within *Pasteurellaceae* has been performed by Dewhirst et al. (1992, 1993). The rRNA branches (*P. multocida*, *A. lignieresii*, *H. influenzae*, *H. aphrophilus*, *A. actinomycetemcomitans*, and *H. ducreyi*) correspond to the 16S rRNA subclusters 3B, 4A, 1C, 1B, 1A, and 2B, respectively (Dewhirst et al., 1993). These findings indicate that the genera defined by DNA–DNA hybrid-

1. Meat blood agar: 500 g of chopped, lean meat cooked for 20 min in 1 liter of water, supplemented with 10 g/l Bacto peptone (Difco, Detroit, USA), 5 g/l NaCl, and 10 g/l bacteriological agar no. 1 (Oxoid, Unipath Ltd., Basingstoke, England), and cooked for 20 min. pH adjusted to 7.7–7.6 by NaOH. Autoclaved at 120°C for 20 min, and 5% calf's blood added at a temperature of 45°C.

ization do not represent phylogenetic groups and that further reorganization within the family is necessary (Angen, 1997).

The close similarity between actinobacilli and the genera *Haemophilus* and *Pasteurella* necessitates comparison of biochemical characters at the species level. Boot and Bisgaard (1995) have reclassified 30 *Pasteurellaceae* strains isolated from rodents. Strains previously reported as *Actinobacillus* spp. have been reclassified as *P. pneumotropica* biotype Jawetz, *P. dagmatis*, or taxon 22. These findings underline the importance of extended characterization of isolates and comparison with reference strains to avoid misclassification within the family *Pasteurellaceae*. The main features of differentiation between these genera and others are given in the *Pasteurellaceae* chapter, Table BXII.γ.287.

Taxonomic Comments

In *Bergey's Manual of Determinative Bacteriology*, 9th Ed. (Holt et al., 1994), the genus *Actinobacillus* included *A. actinomycetemcomitans*, *A. capsulatus*, *A. equuli*, *A. hominis*, *A. lignieresii*, *A. muris*, *A. pleuropneumoniae*, *A. rossii*, *A. seminis*, *A. suis*, and *A. ureae*. The new species *A. minor*, *A. porcinus*, and *A. indolicus*, created by Møller et al. (1996a), and *A. delphinicola*, established by Foster et al. (1996), were later added to the genus. Most recently, *A. scotiae* and *A. succinogenes* have been included in the genus *Actinobacillus* (Foster et al., 1998; Guettler et al., 1999) and Bisgaard Taxon 9 has been classified as *A. arthritidis* and genomospecies 2 (Christensen et al., 2002a).

Within the family *Pasteurellaceae*, genomic relationships have indicated that several groups/complexes stand for new genera: the *H. aphrophilus* group, the *"A. salpingitidis"* group, the *"Histophilus ovis"*/*"H. somnus"* group, and the former *P. haemolytica* and *P. pneumotropica* complexes. The rRNA branches containing *H. aphrophilus*, *A. actinomycetemcomitans*, *H. ducreyi*, and *H. ovis* represent candidates for new genera (De Ley et al., 1990). Based on DNA hybridization data, Escande et al. (1984) and Mutters et al. (1989) have proposed that *Actinobacillus* be limited to *A. lignieresii*, *A. equuli*, *A. capsulatus*, *A. suis*, *A. ureae*, *A. hominis*, *A. pleuropneumoniae*, *A. arthritidis*, and Bisgaard's taxa 5 and 11. 16S rRNA sequencing (Dewhirst et al., 1992) has demonstrated true actinobacilli in cluster 4A, which contains *A. lignieresii*, *A. pleuropneumoniae*, Bisgaard's Taxon 11, *A. ureae*, *A. equuli*, *A. suis*, and *H. parahaemolyticus*. *A. hominis* has subsequently been added (Dewhirst et al., 1993). Sequencing of additional strains includes *A. arthritidis*, Bisgaard's taxa 5, 8, and *P. bettyae* in cluster 4 (Dewhirst et al., 1993). Of these, Bisgaard's taxa 8 and 9 are closely related to *Actinobacillus sensu stricto*. *A. capsulatus* does not cluster with the true actinobacilli (Dewhirst et al., 1992, 1993). This organism, along with *A. seminis*, *P. mairii*, *P. aerogenes*, and *H. paracuniculus*, may represent a new genus within *Pasteurellaceae* (Dewhirst et al., 1993).

Dewhirst et al. (1992) have pointed out that in cluster 4, each species branches slightly deeper than the one above, giving no logical point at which to end the genus *Actinobacillus sensu stricto*. In addition, Møller et al. (1996a) have emphasized the problem of defining natural genera in the family *Pasteurellaceae*, because NAD-dependent species are distributed throughout the family. Although new genera may be warranted to accommodate species such as *A. actinomycetemcomitans*, *H. aphrophilus*, *H. parasuis*, *H. segnis* and others, the natural borders for such genera may not be easy to define. Reorganization without a logical basis may cause unnecessary confusion and frustration among clinical microbiologists (Møller et al. (1996a)).

It is clear from phylogenetic studies that *A. actinomycetemcomitans* is not a true actinobacillus, because *Actinobacillus sensu stricto* falls in cluster 4A and *A. actinomycetemcomitans* in cluster 1A (Dewhirst et al., 1992). Furthermore, the representatives of serotypes a, b, and c of *A. actinomycetemcomitans* diverge in the established phylogenetic tree at a level greater than that seen between many species. This may arrant the establishment of subspecies from these serotypes. However, not all serotypes have yet been sequenced.

According to rRNA–DNA relatedness results (De Ley et al., 1990) and 16S rRNA sequencing data (Dewhirst et al., 1992, 1993), *A. actinomycetemcomitans*, *"A. salpingitidis"*, *A. muris*, and *A. seminis* should be excluded from *Actinobacillus sensu stricto*. *A. actinomycetemcomitans* and *H. aphrophilus* are related to the genus *Haemophilus sensu stricto* (Dewhirst et al., 1992). Because *A. actinomycetemcomitans* is phenotypically different from *Haemophilus* and has a long evolutionary branch, it may be placed in its own genus (Dewhirst et al., 1992). Potts et al. (1985) have suggested that *A. actinomycetemcomitans* be transferred to the genus *Haemophilus*. However, the International Committee on Taxonomy Subcommittee on *Pasteurellaceae* has rejected this proposal because *A. actinomycetemcomitans*, although similar to *H. aphrophilus*, is not convincingly related to *H. influenzae*, the type species of the genus *Haemophilus*. Previously, Kilian (1976) had pointed out that *A. actinomycetemcomitans* and *H. aphrophilus* do not require hemin and NAD for growth and therefore, at that time, did not meet the criteria for inclusion into the genus *Haemophilus*.

Most recently, the Dewhirst group has established a phylogenetic tree for the family *Pasteurellaceae* based on 114 nonredundant 16S rRNA sequences (Family *Pasteurellaceae*, Fig. BXII.γ.215). The tree contains 21 phylogenetic clusters. One of these is the *Actinobacillus sensu stricto*, which contains *A. lignieresii*, *A. suis*, *A. equuli*, *A. hominis*, *A. ureae*, and *A. pleuropneumoniae*. *H. parahaemolyticus* was also included. Some unnamed species, such as Bisgaard Taxa 8 and 9 (*A. arthritidis* and genomospecies 2), have also joined this group, as have taxa represented by strains Kunstyr 570 (MCCM 00149), Bisgaard F64 (CCUG 28015), and SSI P585 (CCUG 19799). The genus *Actinobacillus* should probably include these organisms, as proposed by Escande et al. (1984) and Mutters et al. (1989).

The remaining clusters, except for *Haemophilus sensu stricto*, *Pasteurella sensu stricto*, *Mannheimia*, and *Lonepinella*, contain generically misclassified species of *Actinobacillus*, *Haemophilus*, and *Pasteurella* and unnamed species of *Pasteurellaceae* from a variety of culture collections. Thus, *A. minor* falls with *Haemophilus* "minor group" 202 and *A. pleuropneumoniae* with *H. paraphrohaemolyticus*, each in two subclusters of the Porcine Cluster. *A. rossii* and *A. porcinus* comprises the Rossii Cluster, together with strains considered to be part of the *P. aerogenes* complex, but do not appear with the type strain of *P. aerogenes*, which is in the Seminis Cluster. In addition, the more deeply branching and unstable Bisgaard Taxon 7 may belong to the Rossii Cluster. *A. indolicus* falls in the Parasuis Cluster, together with *H. parasuis* and a taxon represented by *H. parasuis* strain Nagasaki. *A. capsulatus* is contained in the Capsulatus Cluster, together with *H. paracuniculus* and a third taxon represented by *A. capsulatus* strain SSI P796. Previously, DNA–DNA hybridization had placed *A. capsulatus* in the *Actinobacillus sensu stricto* (Escande et al., 1984; Mutters et al., 1989). However, the sequences for five isolates (SSI P243^{T}, P244, P572, P662, and P796) fall in the Capsulatus Cluster. This is in contrast to a horse isolate (SSI P585 [CCUG 19799]), which falls in the middle of the *Actinobacillus sensu stricto* Cluster, as well as a hamster *"A. capsulatus"* strain (MCCM 149) and a duck isolate

(Bisgaard F64 [CCUG 28015]), which form the deepest branch of the *Actinobacillus sensu stricto* Cluster. These findings suggest that *A. capsulatus*-like strains from species other than rabbit might represent unique species. *A. actinomycetemcomitans* falls in the Aphrophilus Cluster, together with *H. segnis*, *H. aphrophilus*, *H. paraphrophilus*, and an *H. segnis*-like taxon represented by strain MCCM 00337. This is consistent with rRNA–DNA studies by De Ley et al. (1990), which suggested that the Aphrophilus Cluster be separated from the *Haemophilus sensu stricto*. *A. seminis* is contained in the Seminis Cluster with *P. mairii* and *P. aerogenes*. The Rodent Cluster comprises 9 species, with *A. muris*, *P. pneumotropica*, and *"H. influenzae-murium"* as named species. This cluster also contains Bisgaard Taxon 17 (rat), strain Kunstyr 507 (MCCM 02120; hamster), Mannheim Michael A (CCUG 28028; guinea pig), Kunstyr 246 (CCUG 28030; hamster), Mannheim A/5a (MCCM 00235; rat), and Forsyth A3 (mouse). *"A. salpingitidis"* falls in the Avian Cluster, together with *P. volantium*, *P. gallinarum*, *P. avium*, *P. anatis*, *H. paragallinarum*, Bisgaard Taxon 2 and 3, *Haemophilus* taxon C, *Pasteurella* species A, and strains representing species such as Wuthe DS 1801 (MCCM 01557), *"Actinobacillus salpingitidis"* CCUG 28018, and *Haemophilus* sp. CCUG 19808. *A. delphinicola* and *A. scotiae* fall in the Ducreyi Cluster, together with *H. ducreyi*, *P. langaa*, and *Phocoenobacter uteri*, while *A. succinogenes* appears in the Somnus Cluster with *"H. somnus"* and Bisgaard Taxon 6 and 10.

Differentiation of the species of the genus *Actinobacillus*

Differential characteristics of species of *Actinobacillus* are given in Tables BXII.γ.291 and BXII.γ.292.

In the following list of *Actinobacillus* species, *A. lignieresii*, *A. suis*, *A. equuli*, *A. hominis*, *A. ureae*, and *A. pleuropneumoniae* are considered species belonging to *Actinobacillus sensu stricto*. The other species in the list are pending placement in other genera of the family *Pasteurellaceae*.

List of species of the genus Actinobacillus

1. **Actinobacillus lignieresii** Brumpt 1910, 849[AL]
lig.ni.e.re' si.i. M.L. gen. n. *lignieresii* of Lignières, named for J. Lignières, one of the bacteriologists who first isolated this organism.

Cells are small and rod-shaped, often showing shorter coccobacillary forms. In media with fermentable carbohydrates such as glucose and maltose, long bacillary or filamentous forms can be seen. Shorter bacillary or filamentous forms are more common on media containing blood or serum. Small granules can be detected scattered among the cells and often lying at the pole of the bacillary or filamentous form. This gives the characteristic "Morse-code" form (Phillips, 1960).

The rods, which measure 1.15–1.25 × 0.4 μm, are nonmotile, nonsporing, and non-acid-fast. Slime, but not a capsule, can be demonstrated in wet India ink preparations. Cells stain easily, particularly with carbol fuchsin. They may show bipolar staining.

Viscous colonies, 1–2 mm in diameter, are formed on primary isolation. The sticky nature of the colonies is lost with repeated subcultivation. The colony size may increase up to 4 mm upon prolonged cultivation. *A. lignieresii* grows on MacConkey agar. There is no hemolysis on sheep blood agar. The growth is poor and not visible for some days in a gelatine stab. There is no liquefaction. Broth cultures are turbid with little deposit. Growth is improved by the addition of serum.

The best fermentation with carbohydrates is obtained in a peptone–Lemco base with 1% carbohydrate and bromothymol blue as an indicator (Holmes, 1998). Tests should not be prolonged beyond 14 d. The organism produces acid without gas promptly from maltose, mannitol, and sucrose, but with a delayed reaction in lactose (5–7 d). Cellobiose, melibiose, rhamnose, salicin, and trehalose are not fermented. Acid is also produced in litmus milk, but no clot is formed. The oxidase reaction is generally positive, while the catalase reaction varies between strains. Esculin and sodium hippurate are not hydrolysed. Produces actinobacillosis in cattle and sheep and has been isolated from an epidural abcess, an intramandibular phlegmon, and an enlarged tongue of a horse. *A. lignieresii* infections in humans bitten by horses or sheep have occurred.

Recently Christensen et al. (2002a) have shown that equine isolates are phenotypically indistinguishable from *A. lignieresii* and that they belong to a separate species tentatively designated genomospecies 1.

The optimum temperature for growth is 37°C. Only slight growth occurs at 20°C and no growth at 44°C.

The mol% G + C of the DNA is: 41.8–42.6 (T_m) (Boháček and Mráz, 1967).

Type strain: ATCC 49236, NCTC 4189.

GenBank accession number (16S rRNA): M75068.

2. **Actinobacillus actinomycetemcomitans** (Klinger 1912) Topley and Wilson 1936, 279[AL] (*Bacterium actinomycetemcomitans* Klinger 1912, 198.)
ac.ti.no.my.ce.tem.co' mi.tans. Gr. n. *actis* a ray; Gr. n. *myces* a fungus; M.L. n. *actinomyces* ray fungus; L. part. adj. *comitans* accompanying; M.L. part. adj. *actinomycetemcomitans* accompanying an actinomycete.

Cells are nonmotile cocci, measuring 0.7 ± 0.1 × 1.0 ± 0.4 μm, or are rod-shaped (Phillips, 1984; Zambon, 1985). They may occur singly, in pairs, or in small clumps. The rod-shaped cells are seen more frequently in agar cultures than in broth or gelatine cultures. While cells may be distinct rod forms in culture, many more coccal forms are seen in actinomycotic lesions.

Colonies on agar are small, <0.5 mm in diameter after 24 h, but enlarge to 2–3 mm after 24 h (Holmes, 1998). They adhere to the agar medium, are difficult to break up, and are described as starlike (Colebrook, 1920; Blix et al., 1990) or like "crossed cigars" (Heinrich and Pulverer, 1959a). Colonies may sometimes have a rough surface and pitting after several days of cultivation. They become mucoid and nonadherent after repeated subculture (Slots, 1982a).

Cells have a microcapsule. Primary broth colonies form tiny, discrete colonies that cling to the sides of glass tubes, while subsequent cultures become less adherent and exhibit uniform turbidity (Zambon, 1985). The organism grows poorly in air but well in 5% CO_2 (capnophilic) or under

anaerobic conditions (Holm, 1954; Slots, 1982a). Optimum growth at 37°C (Heinrich and Pulverer, 1959a).

Slots (1982a) has studied 135 biochemical characters in 6 reference strains of *A. actinomycetemcomitans* and 130 strains freshly isolated from the oral cavity. They all decompose hydrogen peroxide, are oxidase negative and benzidine positive, reduce nitrate, produce strong alkaline and acid phosphatases, and ferment fructose, glucose, and mannose. Variable fermentation results have been obtained with dextrin, maltose, mannitol, and xylose. Carbohydrate fermentation has been used to subgroup *A. actinomycetemcomitans* into 3–10 biochemical groups based on the variable fermentation of key sugars, including dextrin, galactose, maltose, mannitol, and xylose (King and Tatum, 1962; Pulverer and Ko, 1970; Slots et al., 1980). *A. actinomycetemcomitans* is indole negative and produces catalase.

A number of chemotaxonomic techniques have been applied to establish the relationship between *A. actinomycetemcomitans* and closely related species (Olsen, 1993; Olsen et al., 1999). Indigenous to humans where recent evidence implicates *A. actinomycetemcomitans* in the etiology of destructive periodontal diseases. It has also been isolated from abcesses and from cases of actinomycosis, endarteritis, endocarditis, meningitis, pneumonia, septicemia, urinary tract infections, and vertebral osteomyelitis.

The mol% G + C of the DNA is: 42.7 (T_m).

Type strain: ATCC 33384, NCTC 9710.

GenBank accession number (16S rRNA): M75039.

3. **Actinobacillus arthritidis** Christensen, Bisgaard, Angen and Olsen 2002a, 1244[VP]

ar.thri'ti.dis. N.L. fem. gen. n. *arthritidis* of arthritis; from Gr. n. *árthron* joint; L. suff. *-idis* used in names of inflammations.

Cells are pleomorphic without distinct morphology. On bovine blood agar the colonies are nonhemolytic, circular, raised, and regular with an entire margin. The surface of the colonies is generally smooth, shiny, grayish and nontransparent. Mucoid and watery cultures also exist. A diameter of 2–3 mm is often observed after 24 h aerobic incubation at 37°C. The species is positive in the following tests: catalase, oxidase, fermentative reaction in Hugh–Leifson medium with (+)-D-glucose, porphyrin test, nitrate reduction urease, alanine aminopeptidase, phosphatase, ONPG, α-galactosidase, and production of acid from (−)-D-ribose, (+)-D-xylose, (−)-D-mannitol, (−)-D-sorbitol, (−)-D-fructose, (+)-D-galactose, (+)-D-glucose, (+)-D-mannose, lactose, sucrose, and raffinose. Negative results are obtained in Gram staining. Motility at 22 and 37°C, symbiotic growth, β-hemolysis, Simmons citrate, mucate-acid, malonate-base, H_2S/TSI, growth in the presence of KCN, methyl red and Voges–Proskauer at 37°C, production of gas from nitrate, arginine dihydrolase, lysine decarboxylase, ornithine decarboxylase, phenylalanine deaminase, indole production, gelatinase, hydrolysis of Tweens 20 and 80, pigment production, α-glucosidase (PNPG), β-glucosidase (NPG), α-fucosidase, (ONPF), α-glucuronidase (PGUA), α-mannosidase, and β-xylosidase. Negative for production of acid from *m*-erthyritol, adonitol, (+)-D-arabitol, xylitol, (−)-L-xylose, dulcitol, *m*-inositol, (+)-D-fucose, (+)-L-rhamnose, (−)-L-sorbose, cellobiose, trehalose, (+)-D-melezitose, (+)-D-glycogen, inulin, esculin, amygdalin, arbutin, gentiobiose, salicin, (+)-D-turanose, and β-*N*-CH_3 glucosamide. No gas produced from (+)-D-glucose.

Strains of *A. arthritidis* have been isolated from the oral cavity of apparently healthy horses, as well as from diseased foals and horses (mainly those with septicemia and arthritis). Isolates phenotypically indistinguishable from *A. arthritidis*, except for being sorbitol negative are tentatively designated genomospecies 2 (Christensen et al., 2002a.).

The mol% G + C of the DNA is: unknown.

Type strain: Wetmore 1706, ATCC 13376, CCUG 24862.

GenBank accession number (16S rRNA): AF247712.

4. **Actinobacillus capsulatus** Arseculeratne 1962, 38[AL]

cap.su.la'tus. L. n. *capsula* a small chest, capsule; M.L. masc. adj. *capsulatus* encapsulated.

Cells are rod-shaped. Filamentous bacilli that fragment into minute, coccoid bodies are seen in old cultures (Phillips, 1984). Moniliform bodies are formed in 5-d-old cultures on Loeffler's serum. Capsules are present. Primary cultures will not grow on nutrient agar or in nutrient broth. However, subcultures grow as pinpoint colonies or as a faint turbidity. Colonies on sheep blood agar are very sticky. "Flower head" colonies are produced on rabbit blood agar (Phillips, 1984). Growth is sparse on Loeffler's serum, but profuse on Dorset egg, where colonies survive for 10 d. In serum broth, small discrete mural colonies occur.

Optimum temperature is 37°C. No growth at 22°C. Cells are killed after 10 min at 60°C. Differential biochemical characters are given in Tables BXII.γ.291and BXII.γ.292.

A. capsulatus has been isolated from rabbits, hamsters, and snowshoe hares.

The mol% G + C of the DNA is: 42.4 (T_m) (Mannheim et al., 1980).

Type strain: Frederiksen P243, ATCC 51571, NCTC 11408.

GenBank accession number (16S rRNA): M75062.

5. **Actinobacillus delphinicola** Foster, Ross, Malnick, Willems and Garcia 1996, 652[VP]

del.phi.ni'co.la. L. n. *delphinus* dolphin; L. n. *cola* dweller; M.L. n. *delphinicola* dolphin dweller.

Cells are nonmotile, facultatively anaerobic, pleomorphic rods (Foster et al., 1996). Added CO_2 is required for growth.

Colonies on CSBA (Columbia agar supplemented with 5% citrated sheep blood) incubated at 37°C in an atmosphere containing 10% added CO_2 are circular, entire, low, convex, smooth, gray, and 0.75–1 mm in diameter after 24 h. They are nonhemolytic or weakly hemolytic. Blood and serum enhance growth. There is no growth on MacConkey agar. Growth occurs at 42°C, but not at 22°C. Acid is produced from glucose and mannose, but not from adonitol, dulcitol, galactose, inositol, inulin, lactose, maltose, melibiose, raffinose, rhamnose, salicin, sorbitol, sucrose, trehalose, and xylose.

Catalase negative and oxidase positive. Nitrate is not reduced. Voges–Proskauer test is positive. Urease, H_2S, and indole tests are negative. Alkaline phosphatase, esterase–lipase, leucine arylamidase, and acid phosphatase are produced in large amounts. Naphthol-AS-BI-phosphohydrolase is generated, usually in large amounts, and esterase is produced in lesser amounts, as assessed by the API ZYM system.

Some strains may hydrolyze arginine and decarboxylate ornithine and/or lysine. Isolated from harbor porpoises, a Sowerby's beaked whale, and a striped dolphin.

The mol% G + C of the DNA is: not determined.

Type strain: M906/93, NCTC 12870.

GenBank accession number (16S rRNA): X89377.

Additional Remarks: The 16S rRNA sequence is not from the type strain.

6. **Actinobacillus equuli** (van Straaten 1918) Haupt 1934, 513[AL] (*Bacillus equuli* van Straaten 1918, 75.)
e.quu'li. L. n. *equulus* foal; L. gen. n. *equuli* of a foal.

Cells are rod-shaped, but vary markedly depending upon the growth medium. Longer, filamentous forms, similar to those of *A. lignieresii*, are seen when the medium contains glucose or maltose. On nutrient or blood agar, *A. equuli* colonies are so viscous that a string of material is formed between the medium and inoculating loop when an attempt is made to lift the colony from the medium (Holmes, 1998). Stickiness is not lost upon repeated subculturing. When first isolated from clinical material, colonies are usually rough, but they may become smooth on repeated subculture. The viscous character is also present in liquid culture, and it is not lost on repeated subculture.

Growth occurs between 20°C and 39°C. Some strains will grow at 44°C. Glycerol and mannose are usually fermented slowly. Fermentation may be delayed with dextrin, fructose, maltose, melibiose, raffinose, sucrose, trehalose, and xylose. Most strains fail to ferment arabinose, cellobiose, salicin, or sorbitol, but some strains ferment them either promptly or slowly.

Causes "sleepy foal disease". Adult horses may also be infected and abortions may occur in pregnant animals. *A. equuli* may also infect pigs.

The mol% G + C of the DNA is: 40.0–41.8 (T_m) (Boháček and Mráz, 1967).

Type strain: ATCC 19392, NCTC 8529.

GenBank accession number (16S rRNA): M75072.

7. **Actinobacillus hominis** Friis-Møller 1985, 375[VP] (Effective publication: Friis-Møller 1981, 156.)
ho'mi.nis. L. masc. n. *homo* man; L. gen. n. *hominis* of man.

Cells are small, nonmotile, polymorphic rods with small capsules (Friis-Møller, 1981). The capsule is best developed on chocolate agar. On nutrient agar, cultures grow with capsulated and noncapsulated variants. No growth is observed on MacConkey agar and 7.5% salt agar.

On 5% blood agar, colonies are 1.0 mm, grayish-white, and soft mucoid, without hemolysis after 24 h at 35°C. After 24 h, the colonies are flatter, with concentric rings. Colonies are up to 2 mm on nutrient agar, and on chocolate agar are 1.5–2.5 mm and very mucoid. There is no CO_2 or V-factor-requirement. Growth is very poor at 22°C, and no growth is seen at 4°C. In semisolid medium, colonies are facultatively anaerobic.

Strains are CAMP negative and possess very strong alkaline and acid phosphatase and esterase (C_4) activity, as shown by API ZYM tests. Nearly all strains have valine arylamidase and some α-fucosidase activity. All isolates have α-galactosidase and some α-glucosidase activity (Friis-Møller, 1981). Other biochemical characters are listed in Tables BXII.γ.291 and BXII.γ.292. Originally isolated from patients with chronic lung disease, but also isolated from cases of septicemia in hepatic failure, and pleural empyema. Not isolated from animals. Originally isolated from patients with chronic lung disease, but also isolated from cases of septicemia in hepatic failure, and pleural empyema. Not isolated from animals.

The mol% G + C of the DNA is: 40.9 (Bd).

Type strain: P 578, CCUG 19800, ATCC 49457, P578 NCTC 11529.

GenBank accession number (16S rRNA): L06076.

8. **Actinobacillus indolicus** Møller, Fussing, Grimont, Paster, Dewhirst and Kilian 1996a, 956[VP]
in.do'li.cus. M.L. adj. *indolicus* pertaining to indole, which is formed by the organism.

Cells are small rods with lengths varying from 0.8–2.4 µm (Møller et al., 1996a). Colonies are grayish and opaque on chocolate agar and 2 mm in diameter after 48 h of incubation. Cultures have a characteristic pungent smell. Isolates show satellite growth on blood agar plates when cross-inoculated with an appropriate feeder strain.

Galactose, glucose, mannose, maltose, and sucrose are fermented. Arabinose, inulin, esculin, salicin, mannitol, sorbitol, and inositol are not fermented. Lysine and ornithine are not decarboxylated. Cells are V-factor-dependent, X-factor-independent, nonmotile, nonhemolytic, urease negative, and catalase and indole positive.

Isolated from the upper respiratory tracts of pigs.

The mol% G + C of the DNA is: 35.5 (HPLC).

Type strain: 46KC2, CIP 105316, CCUG 39029.

GenBank accession number (16S rRNA): U65584.

9. **Actinobacillus minor** Møller, Fussing, Grimont, Paster, Dewhirst and Kilian 1996a, 955[VP]
mi'nor. L. comp. adj. *minor* less, smaller, referring to the name of this taxon used previously (Møller and Kilian, 1990).

Cells appear as small rods, varying in length from 1.6 to 2.4 µm. They are V-factor-dependent but X-factor-independent. Furthermore, they are nonmotile, nonhemolytic, urease positive, and indole negative. Colonies on chocolate agar are smooth, grayish, and approximately 0.8 mm in diameter after 48 h of incubation. Isolates show satellite growth on blood agar plates when cross-inoculated with a nurse strain. Glucose, mannose, maltose, sucrose, and raffinose are fermented, but arabinose, inulin, esculin, mannitol, sorbitol, and inositol are not. Lysine and ornithine are not decarboxylated. *A. minor* has been isolated from the upper respiratory tracts of pigs.

The mol% G + C of the DNA is: 38.2 (HPLC).

Type strain: NM305, CIP 105314, CCUG 38923.

GenBank accession number (16S rRNA): U65582.

10. **Actinobacillus muris** Bisgaard 1988, 220[VP] (Effective publication: Bisgaard 1986, 1)
mu'ris. L. n. *mus* the mouse; L. gen. n. *muris* of the mouse.

The name *Actinobacillus muris* was used by Wilson and Miles (1964) as a name for the organism called *Streptobacillus moniliformis*. It was clearly a junior synonym and therefore illegitimate (Bisgaard, 1986). Bisgaard (1986) proposed the name *A. muris* for the organism listed here, since it was not on the Approved List of Bacterial Names.

Cells are nonmotile rods. The type strain is identical to

P. ureae strain Ackerman 80–443D (Ackerman and Fox, 1981). Surface cultures on bovine blood agar are circular, low convex, and regular with an entire margin (Bisgaard, 1986). Colonies have a smooth, shiny, opaque, and grayish surface and, at 37°C, reach a diameter of 1.5–2.0 mm after 24 h and 3.5–4.0 mm after 48 h. No hemolysis. Growth is butyrous and easily emulsified and cultures have no characteristic odor. Colonies are easily removed from the agar surface.

Ribose, mannitol, fructose, glucose, mannose, cellobiose, maltose, melibiose, sucrose, trehalose, melezitose, raffinose, and salicin are fermented. Catalase, oxidase, nitrate, and urease tests are positive.

The genome molecular mass is 1.4×10^9 Da (Bisgaard, 1986). *A. muris* has been isolated from the pharynx, uteri, and vaginas of mice.

The mol% G + C of the DNA is: 46.9 (T_m) (Piechulla et al., 1985a).

Type strain: Ackerman 80-443D, ATCC 49577, CCUG 16938, NCTC 12432.

GenBank accession number (16S rRNA): AF024526.

11. **Actinobacillus pleuropneumoniae** (Shope 1964) Pohl, Bertschinger, Frederiksen and Mannheim 1983, 513[VP] (*Haemophilus pleuropneumoniae* Shope 1964, 362.)
pleu.ro.pneu.mo′niae. Gr. n. *pleura* lung, sac; Gr. n. *pneumon* the lungs; M.L. fem. gen. n. *pleuropneumoniae* of pleuropneumonia.

Matthews and Pattison (1961) were the first to describe this organism, but they called it *H. parainfluenzae* and did not propose a new species (Kilian and Biberstein, 1984). Pohl et al. (1983) transferred the organism from the genus *Haemophilus* to *Actinobacillus* on the basis of phenotypic and DNA relatedness. It contains two provisional biotypes. Biovar 1 consists of V-factor-dependent strains hitherto classified as *H. pleuropneumoniae* (Matthews and Pattison) Shope strains, as described by Kilian et al. (1978), with strain Shope 4074 (CCM 5869 ATCC 27088) as the type strain. Biovar 2 consists of V-factor-independent strains and is represented by strain Bertschinger 2008/76 Frederiksen P597 = HIM 677-314.

According to the emended description by Pohl et al. (1983), cells are nonmotile, nonsporeforming, small, and coccoid to rod-shaped, occurring singly, in pairs, or in short chains. Cells are not acid-fast and contain demethylmenaquinone and ubiquinone.

Colonies on chocolate agar are smooth and grayish white and reach 3 mm in diameter after 48 h in a candle jar at 37°C. On bovine or sheep blood agar, the majority of isolates produce a narrow zone of complete hemolysis. The hemolysin acts synergistically with *Staphylococcus aureus* β-toxin, resulting in a positive CAMP reaction. Capsulated strains produce iridescent colonies on clear agar media (e.g., Levinthal's agar and PPLO agar). Biovar 1 isolates show satellite growth on blood agar plates when cross-inoculated with a nurse strain.

Aerobic, microaerophilic in primary isolation, facultatively anaerobic. No additional CO_2 is required for growth in subculture. Mesophilic. Chemoorganotrophic, with pronounced growth response to fermentable carbohydrates in peptone media. Minimal nutritional requirements are not known.

Biovar 1 is the dominant cause of porcine pleuropneumonia around the world. A total of 14 serovars have been recognized (and biovars 1 and 5 subdivided into 1a, 1b and 5a, 5b, respectively [Nielsen, 1990; Nielsen et al., 1997b]). X factors are not required. Attention is drawn to the cultural resemblance of *A. pleuropneumoniae* biovar 2 to *A. suis* and *Mannheimia varigena* (Bisgaard's Taxon 15) (Angen et al., 1999a; Genus *Pasteurella*, this edition).

Some biochemical reactions are given in Tables BXII.γ.291 and BXII.γ.292. A urease-negative variant of *A. pleuropneumoniae* has been described (Blanchard et al., 1993).

The mol% G + C of the DNA is: 43.2 or 42.2 (T_m) (Kilian et al., 1978); 42.2 (T_m) (strain Bertschinger 2008/76).

Type strain: 4074, ATCC 27088, NCTC 12370.

GenBank accession number (16S rRNA): M75074.

Additional Remarks: GenBank accession number for 16S rRNA of MCCM 00189 is AF224283.

12. **Actinobacillus porcinus** Møller, Fussing, Grimont, Paster, Dewhirst and Kilian 1996a, 956[VP]
por.ci′nus. M.L. adj. *porcinus* pertaining to pigs, hogs.

Cells are small rods (length 0.2–2.4 μm) (Møller et al., 1996a). Colonies on chocolate agar are smooth and translucent to grayish. Some isolates grow poorly on chocolate agar, and their colonies are only 0.2 mm in diameter. Others grow readily on chocolate agar and form colonies that are approximately 0.6 mm in diameter after 48 h of incubation. Isolates show satellite growth on blood agar plates when cross-inoculated with a nurse strain. The fermentation of most carbohydrates is variable. No fermentation of inulin, esculin, and salicin. *A. porcinus* is V-factor-dependent, X-factor-independent, nonmotile, nonhemolytic, and urease, catalase, and indole negative. Lysine and ornithine are not decarboxylated. Isolated from the upper respiratory tracts of pigs.

The mol% G + C of the DNA is: 41.4 (HPLC).

Type strain: NM319, CIP 105315, CCUG 38924.

GenBank accession number (16S rRNA): U65583.

13. **Actinobacillus rossii** Sneath and Stevens 1990, 151[VP]
ros.si′i. M.L. gen. n. *rossii* of Ross, named after R.F. Ross, who, with his colleagues, isolated the organism (Ross et al., 1972).

Phenon 17 of Sneath and Stevens (1985); group "Ross" of Kilian and Frederiksen (1981b).

Cells are small, nonmotile bacilli, seldom coccobacilli that are often >2 mm long (Sneath and Stevens, 1990). Endospores are not formed. Growth is aerobic and facultatively anaerobic. Mesophilic. Surface colonies grown aerobically on sheep blood agar are round, grayish, semitransparent, and about 2 mm in diameter after 48 h at 37°C. Occasionally, weak hemolysis without marked greening of the erythrocytes is seen. *A. rossii* produces acid from inositol and sorbitol, but not from sucrose. The organism also reduces Janus green (Sneath and Stevens, 1985). Isolated from the vaginas of postparturient sows and aborted piglets.

The mol% G + C of the DNA is: 41.9 (T_m) (Mannheim et al., 1980).

Type strain: ATCC 27072, NCTC 10801.

14. **Actinobacillus scotiae** Foster, Ross, Patterson, Hutson and Collins 1998, 933[VP]

sco.ti.ae. L. n. *scotiae* classical Latin name of Scotland; L. gen. n. *scotiae* of Scotland, where the isolates were collected from porpoises.

Cells are pleomorphic, nonmotile, Gram-negative rods. They are facultatively anaerobic. Added CO_2 is required for growth. Colonies on Columbia agar (Difco) supplemented with 5% citrated sheep blood that are incubated at 37°C in an atmosphere of 10% added CO_2 are 0.5 mm in diameter after 24 h. They are weakly hemolytic. Blood or serum enhances growth. No requirement of X or V factors. No growth on MacConkey agar. Growth occurs at 25°C, but not at 42°C. Catalase negative and oxidase positive. Nitrate is reduced. Acid is produced from glucose, lactose, and maltose, but not from adonitol, arabinose, dulcitol, inositol, mannose, melibiose, raffinose, rhamnose, salicin, sorbitol, sucrose, trehalose, or xylose. Some strains produce acid from galactose. Urease and Voges–Proskauer positive, but indole negative. Some strains generate ornithine decarboxylase. Lysine decarboxylase and arginine dihydrolase are not produced. The type strain is positive for ornithine decarboxylase and negative for acid production from galactose. *A. scotiae* has been isolated from porpoises.

The mol% G + C of the DNA is: 40.5 (T_m).

Type strain: M2000/95/1, ATCC 27072, NCTC 12922.

GenBank accession number (16S rRNA): Y09653.

15. **Actinobacillus seminis** (ex Baynes and Simmons 1960) Sneath and Stevens 1990, 151[VP]

sem.i'nis. L. n. *semen* seed; L. gen. n. *seminis* of semen.

Phenon 14 of Sneath and Stevens (1985); *"Actinobacillus seminis"* of Kilian and Frederiksen (1981b) and Phillips (1984).

Cells are small, nonmotile bacilli and coccobacilli that are often >2 μm long (Sneath and Stevens, 1990). Gram reaction is negative. Endospores are not formed. Growth is aerobic and facultatively anaerobic, as well as mesophilic. On first isolation, 5% CO_2 is often required. On sheep blood agar, surface colonies grown aerobically are round, grayish, semitransparent, and about 1 mm in diameter after 48 h at 37°C. Colonies do not produce hemolysis, but sometimes produce greening of the erythrocytes. *A. seminis* has been associated with epididymitis and orchitis in rams; ovine contagious epididymitis; mastitis in ewes; and polyarthritis, posthitis, and abortion in sheep.

A. seminis has been associated with epididymitis and orchitis in rams; ovine contagious epididymitis; mastitis in ewes; and polyarthritis, posthitis, and abortion in sheep.

The organism produces slow and weak fermentation of carbohydrates and no acid from mannose. It also gives a negative phosphatase reaction (Sneath and Stevens, 1985).

The mol% G + C of the DNA is: 43.7 (T_m) (Mannheim et al., 1980).

Type strain: ATCC 15768, NCTC 10851.

GenBank accession number (16S rRNA): M75047.

16. **Actinobacillus succinogenes** Guettler, Rumler and Jain 1999, 214[VP]

suc.ci.no'ge.nes. M.L. n. *acidum succinicum* succinic acid; Gr. v. *gennaio* to produce; M.L. adj. *succinogenes* succinic-acid-producing.

Cells are nonmotile, pleomorphic, Gram-negative rods (0.8 × 1 μm). Filamentous cells are occasionally seen. "Morse code" forms and chains are common in actively growing broth cultures. Cells within an extracellular matrix are common in aerobically grown cultures. Chemoorganotrophic. Yeast extract and CO_2 stimulate growth. Colonies on TSB agar are circular, entire, gray, translucent, and 1–1.5 mm in diameter after 24 h incubation at 37°C with CO_2. Growth occurs at 37–39°C, but not at 20°C or 45°C. Catalase and oxidase positive. Alkaline phosphatase positive. Acid, but not gas, is produced from glucose and fructose within 24 h. Acid is also produced from arabinose, ribose, xylose, galactose, mannose, mannitol, sorbitol, amygdalin, arbutin, esculin, salicin, cellobiose, maltose, lactose, sucrose, raffinose, β-gentiobiose, arabitol, gluconate, and 5-ketogluconate. Acid is not produced from dulcitol, inositol, inulin, glycerol, erythritol, arabinose, xylose, adonitol, methyl β-xyloside, sorbose, rhamnose, methyl α-D-mannoside, methyl α-D-glucoside, *N*-acetylglucosamine, melibiose, trehalose, melezitose, amidon, glycogen, xylitol, turanose, xylose, tagatose, fucose, arabitol, and 2-ketogluconate. β-Galactosidase, arginine-β-arylamidase, and leucine arylamidase are produced in large amounts. Nitrates are reduced to nitrites. Indole and urease are not produced. Rapid and extensive growth is observed when utilizing arabinose, cellobiose, fructose, galactose, glucose, lactose, maltose, mannitol, mannose, sucrose, xylose, or salicin in media with yeast extract and corn steep liquor. Marked production of succinic acid in presence of CO_2 and high substrate concentration. *A. succinogenes* has been cultured from the bovine rumen.

The mol% G + C of the DNA is: 45 (HPLC) (Mesbah et al., 1989).

Type strain: 130Z, ATCC 55618.

GenBank accession number (16S rRNA): AF024525.

17. **Actinobacillus suis** van Dorssen and Jaartsveld 1962, 456[AL]

su'is. L. n. *sus* the pig, swine; L. gen. n. *suis* of the pig.

Cells are usually rod-shaped. Considerable variability may be seen, with long rods and filaments of variable length among cells grown on media both with and without glucose. Colonies on nutrient agar or blood agar are sticky and adhere to the medium. Growth is less viscous than in *A. equuli*. Stickiness increases with prolonged incubation of up to 72 h. In older colonies, a transparent border zone is developed, giving the appearance of a fried egg. The marked adherence to the medium may be lost upon repeated subculturing. Viscous growth also occurs in nutrient broth, but is not so marked as in *A. equuli*. After centrifugation, broth-grown sedimented cells are creamy yellow. Nutrient agar and nutrient broth cultures die within 15 d at 4°C.

A. suis usually ferments arabinose, dextrin, and galactose promptly, but a few strains may show slow fermentation with these substrates. Acid is also formed from cellobiose, lactose, maltose, melibiose, salicin, and sucrose, but not from mannitol and rhamnose. Glycerol and mannose are usually slowly fermented. Most strains of *A. suis* (and *A. equuli*), but not *A. lignieresii*, ferment melibiose and trehalose (Holmes, 1998). All strains of *A. suis*, but no strains of *A. equuli* and *A. lignieresii*, hydrolyze esculin. *A. suis* is an opportunistic pathogen of swine. Human infections have been reported as the result of pig bites.

The mol% G + C of the DNA is: 40.5 (T_m) (Mráz, 1968).

Type strain: ATCC 33415, CCM 5586.

GenBank accession number (16S rRNA): AF015299.

18. **Actinobacillus ureae** (Jones 1962) Mutters, Pohl and Mannheim 1986, 343[VP] (*Pasteurella ureae* Jones 1962, 150.)
u.re' ae. Gr. n. *urum* urine; M.L. gen. n. *ureae* of urine.

Cells are small, rod-shaped, and pleomorphic depending on the growth medium. Occasionally, bipolar staining is seen. Growth is best on media containing blood or serum. It occurs from 25–40°C, with optimal growth at 37°C. Differential biochemical characters are given in Tables BXII.γ.291 and BXII.γ.292. *A. ureae* occurs infrequently in the noses of healthy humans and occasionally causes ozaena and other infections in the respiratory tract.

The mol% G + C of the DNA is: 41.2–43.7 (T_m) (Pohl, 1979; Mutters et al., 1984).

Type strain: Henriksen 3520/59, ATCC 25976, NCTC 10219.

GenBank accession number (16S rRNA): M75075.

19. **"Actinobacillus salpingitidis"** (Kohlert 1968) Mráz, Vladík and Bohácek 1976.

Cells are coccobacteria of 0.5 ± 0.1 × 1.5 ± 0.5 μm, with a tendency for bipolar staining (Mráz et al. 1976). Longer polymorphic rods and curved filaments occur. In the microscope, cells appear individually, in pairs, and in short chains. Long chains can be found in broth cultures. Nonmotile. Gram negative.

Colonies on nutrient agar are 0.1 mm in diameter. Some strains show a mixture of colony sizes (0.1–0.5 mm). They glisten in transmitted light. Older colonies of larger types reach 1 mm and acquire a grayish appearance. Colonies on nutrient agar with sheep's blood are 0.2–1 mm in diameter, exhibiting a 0.5–1.5 mm zone of expressive or total hemolysis. After 2 d of incubation, they measure 0.5–2 mm. The larger zones turn grayish and have an umbonate profile. Colonies on nutrient agar with lamb's blood, according to Smith (1962), have a simple zone of expressive or total hemolysis. MacConkey agar with crystal violet (BioQuest) yields visible growth during 48 h of incubation. Endo agar provides no growth, except in sporadic cases. Nutrient broth yields homogeneous or fine-granulated turbidity with possible larger flakes. From the third day of incubation, a whitish-gray sediment is formed. With slight shaking the content of the test tube may be easily redispersed. Growth in litmus milk gives no changes or sporadic delayed discoloration.

Metabolism is fermentative. During 2 days of incubation, acid, but no gas, is formed from glucose, xylose, levulose, mannose, galactose, saccharose, trehalose, and mannitol; within 14 d acid is also formed from lactose (3–12 d), raffinose (2–10 d), and glycerol (2–7 d). Results are variable and, for a great part, delayed for arabinose, maltose, inulin, starch, dextrin, sorbitol, and inositol, while rhamnose, cellobiose, melibiose, adonitol, dulcitol, salicin, and esculin remain negative.

Nitrites are produced from nitrates. Urea is not hydrolysed. Indole is not produced. Hydrogen production is variable. The methyl red test is negative. Acetoin is not produced. Ammonia production is variable. Catalase is positive. Oxidase is usually positive, and cytochrome oxidase is negative. Arginine dihydrolase and lysine and ornithine decarboxylases are negative. β-Galactosidase is positive. Facultatively anaerobic. Growth at 30–40°C. Temperature optimum is 37°C. Isolated from the respiratory tract and oviduct of healthy domestic fowl, from salpingo-peritonitis in hens, and from the organs of dead chicks and young turkeys.

The mol% G + C of the DNA is: 39.6–42.9; mean value 41.5 (T_m).

Deposited strain:

GenBank accession number (16S rRNA): L06077.

Additional Remarks: Suggested neotype strain: CCM 5974 (strain 556/71 of Mráz et al., 1976) = CCUG 23139.

Genus III. Haemophilus *Winslow, Broadhurst, Buchanan, Krumwiede, Rogers and Smith 1917, 561*[AL]

MOGENS KILIAN

Hae.mo' phi.lus. Gr. n. *haima* blood; Gr. n. *philos* lover; M.L masc. *Haemophilus* blood-lover.

Minute to medium-sized **coccobacilli or rods**, generally less than 1 μm in width and variable in length, sometimes forming threads or filaments and showing **marked pleomorphism**. Gram negative. **Nonmotile. Aerobic or facultatively anaerobic. Require preformed growth factors present in blood**, particularly X factor (protoporphyrin IX or protoheme) and/or V factor (nicotinamide adenine dinucleotide [NAD] or NAD phosphate [NADP]). Even after specific growth factors have been provided, growth is best on complex media. Optimum temperature, 35–37°C. **Nitrates are reduced to or beyond nitrites.** Oxidase and catalase reactions vary among strains. **Chemoorganotrophic. All species can attack carbohydrates fermentatively**, yielding acetic, lactic, and succinic acids as end products in glucose broth. Occur as **obligate parasites on the mucous membranes of humans and a variety of animal species**. Several 16S rRNA sequence signatures for the family *Pasteurellaceae* have been demonstrated, but none of these is specific for the genus *Haemophilus* as presently defined (Dewhirst et al., 1992).

The mol% G + C of the DNA is: 37–44.

Type species: **Haemophilus influenzae** (Lehmann and Neumann 1896) Winslow, Broadhurst, Buchanan, Krumwiede, Rogers, and Smith 1917, 561 (*Bacterium influenzae* Lehmann and Neumann 1896, 187.)

FURTHER DESCRIPTIVE INFORMATION

Phylogenetic position The genus *Haemophilus* is located in the *Gammaproteobacteria* and is a member of the family *Pasteurellaceae* (Sneath and Johnson, 1973; Pohl, 1979, 1981a; Mannheim et al., 1980; Mannheim 1981; Chuba et al., 1988; De Ley et al., 1990; Dewhirst et al., 1992, 1993).

Cell morphology Cells of *Haemophilus* species tend to occur as individual short rods or coccobacilli. Filament formation is environmentally influenced and develops as cultures age and are under less than optimum conditions of growth (Fig. BXII.γ.216). Capsules are present in some species, notably *H. influenzae*, *H.*

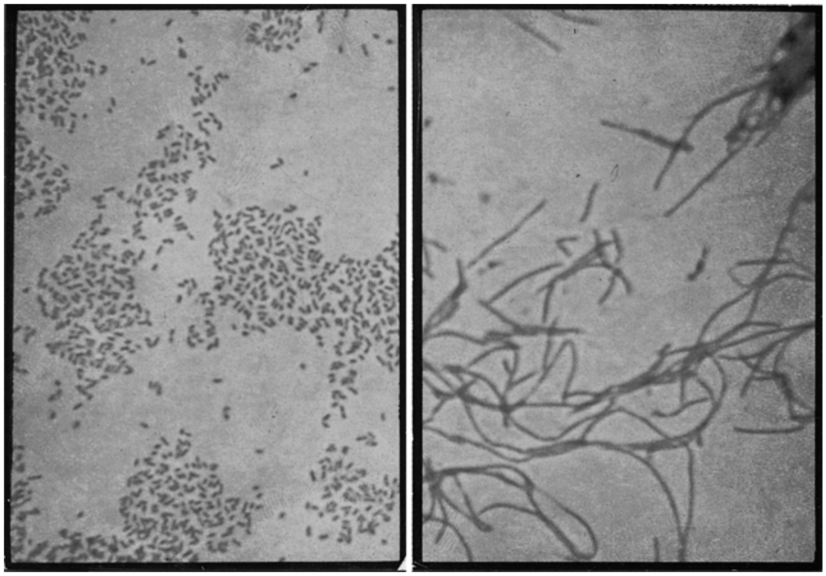

FIGURE BXII.γ.216. Cell morphology of a strain of *H. influenzae* (*left*) and a strain of *H. parainfluenzae* (*right*), illustrating the extent of pleomorphism that may be observed in bacteria belonging to this genus.

paragallinarum, and *H. parasuis* and are of particular interest in *H. influenzae* and *H. paragallinarum*, where they play a part in pathogenesis, determination of type specificity, and induction of anti-infective immunity. Occasional capsulate strains of *H. parainfluenzae* have been described (Sims, 1970).

Cytoplasmic membrane composition The membrane phospholipids of *Haemophilus* spp. are similar to those of other Gram-negative bacteria, with phosphatidylethanolamine being the major type. Smaller quantities of phosphatidylglycerine have also been detected. It has been suggested that trace amounts of lysophosphatidylethanolamine may be a characteristic marker of *Pasteurellaceae* in general (Mutters et al., 1993).

Cell wall composition The cell walls resemble those of other Gram-negative bacteria in structure, composition, and endotoxic activity. Unlike the lipopolysaccharide (LPS) of *Enterobacteriaceae*, *H. influenzae* LPS lacks long polysaccharide O chains and, thus, may be described more accurately as a lipooligosaccharide (LOS). It consists of a membrane-anchoring lipid A, an inner core of a singly phosphorylated 2-keto-3-deoxyoctulosonic acid (KDO) linked to three heptose molecules, and an outer core oligosaccharide consisting of a heteropolymer of glucose and galactose and a sialylated terminal lactosamine (Zamze and Moxon, 1987; Phillips et al. 1993; Roche and Moxon, 1995; Risberg et al., 1997). There is marked intra- and inter-strain heterogeneity in the composition and linkage of these saccharide units in the outer core of *H. influenzae* LPS and hence in the epitopes expressed (van Alphen et al., 1990; Roche and Moxon, 1995). The lipid A backbone is a glucosamine disaccharide substituted by two phosphate groups, as in enterobacterial lipid A, but with a simpler fatty acid composition of only tetradecanoic acid and its 3-hydroxylated derivative (Maskell et al., 1992). KDO is present in lesser amounts than in the LPS of *Enterobacteriaceae*: 0.4–1.5% of LPS in *H. influenzae*, compared to 5–8% in *Salmonella* spp. (Flesher and Insel, 1978).

Numerous genes are involved in the LPS biosynthesis by *H. influenzae*. These include the *lic* genes organized in three chromosomal loci (*lic1*, *lic2*, and *lic3*) (Weiser et al., 1990; Maskell et al., 1992; Hood et al., 1996). The first gene (*lic1A*, *lic2A*, *lic3A*) of each of these multigene loci contains variable numbers of tandem repeats of the tetramer CAAT which, by facilitating slipped-strand mispairing, are responsible for the variable expression of LPS epitopes (Weiser et al., 1989; Maskell et al., 1992; High et al., 1996). An additional source of variation is the on–off switching in the expression of phosphorylcholine (ChoP). Choline is taken up from the environment by *H. influenzae* and incorporated into its LPS as ChoP under control of the *licA* gene in the *lic1* locus. The translational switch is based on variation in the number of CAAT repeats in the *licA* gene (Kolberg et al., 1997; Weiser et al., 1997). The frequency of spontaneous, reversible gain and loss (phase variation) of LPS oligosaccharide epitopes expressed by genes in the three chromosomal loci *lic1*, *lic2*, and *lic3* is 10^{-2}–10^{-3}/generation (Weiser et al., 1990).

As in other members of the family *Pasteurellaceae*, the number of cell wall fatty acids found in *Haemophilus* species is comparatively low. The general pattern is characterized by relatively large amounts of *n*-tetradecanoate ($C_{14:0}$), 3-hydroxy-tetradecanoate ($C_{14:0\ 3OH}$), hexadecanoate ($C_{16:1}$), and *n*-hexadecanoate ($C_{16:0}$). The three C_{18} fatty acids, octadecadienoate ($C_{18:2}$), octadecenoate ($C_{18:1}$), and *n*-octadecanoate ($C_{18:0}$) are also present, but in low concentrations. Small species-to-species variations in the relative amounts of these fatty acids have been demonstrated, but discrimination based on such differences cannot be achieved (Jantzen et al., 1981; Brondz and Olsen, 1984b; Brondz and Olsen, 1989; Mutters et al., 1993).

Analyses of polyamine patterns of whole cells of representative strains of species within the family *Pasteurellaceae* reveal unexpected diversity compared to that observed for other Gram-negative rods. At least seven different polyamine patterns are present among members of the family. All current species of *Haemophilus*, with the exception of *H. felis*, show a predominance of 1,3-diaminopropane (Table BXII.γ.293) (Busse et al., 1997). However, the extent of intra-species diversity is not yet known.

Outer membrane proteins (OMPs) have been the subject of significant interest, particularly in *H. influenzae*, as a means of typing and as potential vaccine candidates. There have been 25–

[b]Abbreviations: DAP, 1,3-diaminopropane; PUT, putrescine; CAD, cadaverine; TYR, tyramine; NSPD, *sym*-norspermidine; SPD, spermidine; HSPD, *sym*-homospermidine; SPM, spermidine; tr, trace (less than 0.05 mmol/g dry weight).

35 OMPs detected in *H. influenzae* strains, with only a few accounting for 80% of the total OMPs (Loeb and Smith, 1982). The nomenclature of the major proteins has been reviewed by van Alphen (1993). The major OMPs are P1 (MW 43-50 kDa), P2 (a doublet of MW 43-50 kDa with porin activity), P4 (a lipoprotein of MW 30 kDa), P5 (2 conformers of the same protein), and P6 (a lipoprotein of MW 16.6 kDa). The protein originally designated P3 consists of both the non-heat-modified form of P1 and the heat-modified form of P5. The size polymorphism of proteins P1, P2, and P5 forms the basis for OMP typing of *H. influenzae*. While P2 is conserved in *H. influenzae* serovar b strains, it is extremely diverse and shows antigenic drift in noncapsulated strains (Duim et al., 1994; Murphy, 1994). P4 and P6 are reported to be conserved in *H. influenzae* (Granoff and Munson, 1986; Nelson et al., 1988; Barenkamp, 1992; van Alphen, 1993; Gilsdorf, 1998). OMP profile diversity has also been detected among isolates of *H. paragallinarum* (Blackall et al., 1990b).

Stable wall-deficient variants (L-forms) have been produced experimentally from *H. influenzae* (Roberts et al., 1974).

Fine structure The cell wall of *Haemophilus* species is typical of Gram-negative bacteria, having an ultrastructure composed of multiple wavy outer membranes and a poorly defined plasma membrane, with an intervening electron-transparent space (Sherwin and Wilkins, 1973; Kilian and Theilade, 1975; Doern and Buckmire, 1976; Kilian and Theilade, 1978; Holt et al., 1980). The entire cell wall, including the cell membrane, averages 20 nm in thickness. Vesicular structures ("blebs") have been demonstrated on the outer wall of several *Haemophilus* species (Holt et al., 1980). These are morphologically identical to lipopolysaccharide vesicles and are released into the surroundings. Methods for the isolation of the inner and outer membranes from *H. influenzae* serovar b cells have been devised by Loeb et al. (1981).

Fresh clinical isolates of *H. influenzae* usually express peritrichous pili with hemagglutinating properties. However, after serial subcultivations most isolates, either capsular or noncapsular, do not express such pili. Exceptions are *H. aegyptius* and the original Brazilian purpuric fever (BPF)-associated clone of *H. influenzae*, which are more stably piliated (Gilsdorf et al. 1997; Read et al., 1998). The hemagglutinating pili are 4.7–18 nm in diameter and 209–453 nm in length, with a hollow core. They are composed of a pilin protein subunit of M_r 21,000. Pilus expression is governed by a 5-gene operon (*hifA–hifE*) and oscillates between phase off and phase on at a rate of about 10^{-4}/generation. This phase variation is likely due to slip-strand mispairing in a poly(TA) dinucleotide tract that separates the divergent, bidirectional *hifA* and *hifB–E* promoters, altering the spacing upstream of the transcriptional start sites (van Ham et al., 1993). Some strains, including the previously mentioned conjunctival *Haemophilus* taxa (*H. aegyptius* and BPF-clone), possess duplicated pilus gene clusters, which may explain the higher stability of pilus expression (Read et al., 1998). In addition to the hemagglutinating pili, other types of adherence organelles that do not mediate hemagglutination have been described for *H. influenzae* (Jacques and Paradis, 1998). Some strains of *H. influenzae* biotype IV, which constitute a distinct evolutionary lineage (see below) and may be isolated from neonatal infections or the female genital tract, possess peritrichous pili that do not hemagglutinate, but mediate binding to HeLa cells (Rosenau et al., 1993). Fimbrial structures that are thinner than pili have been demonstrated in otitis media isolates of noncapsular *H. influenzae* (Bakaletz et al., 1988). In addition, different morphological types of hemagglutinating and non-hemagglutinating pili were described by Brinton et al. (1989), but their relationship to those mentioned above has not been clarified. Fine tangled pili composed of a unique major protein subunit of M_r 24 kDa have been described in strains of *H. ducreyi* (Brentjens et al., 1996). Surface-associated thin hairlike structures of an unidentified nature have been demonstrated in *H. aphrophilus*, *H. paraphrophilus* (Holt et al., 1980), occasional strains of *H. parainfluenzae* (Kahn and Gromkova, 1981), and *H. parasuis* (Munch et al., 1992).

Colonial and cultural characters Surface colonies of *Haemophilus* species on sufficiently rich media are usually nonpigmented or slightly yellowish, flat, and convex, and they attain a diameter of 0.5–2.0 mm within 48 h at 37°C. *H. influenzae* undergoes spontaneous phase variation in colony opacity. Weiser et al. (1995) have identified a gene locus that contributes to opacity variation and is associated with the ability to colonize the nasopharynx of infant rats. Most species produce smooth colonies, but some variation is seen, particularly in *H. parainfluenzae* and *H. aphrophilus*. Some species show β hemolysis on blood agar (see Table BXII.γ.294). Growth in broth media usually shows even turbidity, but strains of *H. aphrophilus*, *H. paraphrophilus*, and *H. parainfluenzae* show granular growth with heavy deposits, due to aggregation of cells.

Nutrition and growth conditions Apart from the specific growth factor requirements, the various species of *Haemophilus* exhibit some variation in their nutritional needs and preferred growth conditions. The most universally satisfactory propagative media are chocolate agar and Levinthal media (agar and broth). The former has the virtue of relative ease of preparation, the latter that of transparency, which facilitates the recognition of colonial phases and dissociation phenomena. Colonial iridescence, a property highly correlated with encapsulation, is most readily recognized on Levinthal's agar.

The most critical ingredients of any medium for *Haemophilus* spp., whether for propagation or for characterization, are the growth factors X and/or V ("vitamin-like"). All members of the genus require one or both of these growth factors (few exceptional isolates, see below), and the exact requirement is one of the key characteristics of the individual species (see Table BXII.γ.294). X factor is usually protoporphyrin IX but, under conditions where iron cannot be obtained from another source, the iron-containing protoheme is required (Lwoff and Lwoff, 1937; White and Granick, 1963; Pidcock et al., 1988). Blood or blood derivatives, including hemin, are the traditional and adequate sources of X factor. The customary 5% blood used in blood and chocolate agar is ample. When crystalline hemin is used, required amounts vary between 0.1 and 10 μg/ml for *H. influenzae* (Gilder and Granick, 1947; Brumfitt, 1959; Biberstein and Spencer, 1962; Evans et al., 1974), while the optimum is 200 μg/ml for *H. ducreyi* (Hammond et al., 1978a). The X factor is heat stable and remains active in autoclaved media. The requirement for X factor is substantially reduced, but not eliminated, during anaerobic growth (Gilder and Granick, 1947). The X factor requirement is due to lack of some or all of the enzymes involved in the biosynthesis of protoporphyrin from δ-aminolevulinic acid (Biberstein et al., 1963; White and Granick, 1963) (Fig. BXII.γ.217). Isolates of *H. aphrophilus* often become independent of X factor upon subcultivation (King and Tatum, 1962; Sutter and Finegold, 1970; Kilian, 1976). The biochemical basis for this is not known, but it may suggest that the apparent X

[b]Some strains of *H. parainfluenzae* biovar II show weak (w) hemolysis.

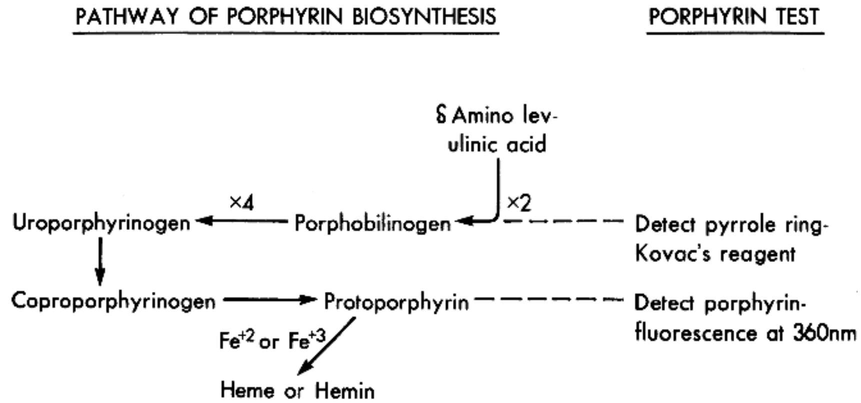

FIGURE BXII.γ.217. Steps in the biosynthesis of heme, with indications of compounds that are demonstrated in the Porphyrin test for X-factor requirement.

factor dependency in fresh isolates of *H. aphrophilus* is not due to the enzyme deficiencies in the porphyrin biosynthetic pathway described for *H. influenzae*. Indeed, White and Granick (1963) reported that one of Khairat's (1940) original isolates had all the enzymes of the biosynthetic pathway characteristic for hemin-independent species.

The V factor is minimally equivalent to nicotinamide mononucleotide (NMN) or nicotinamide riboside (NR), but is usually described as nicotinamide adenine dinucleotide (NAD). It is questionable if NAD phosphate (NADP) can serve as a general substitute for NAD (O'Reilly and Niven, 1986). Pyridine compounds that can serve as V factor can be characterized by possession of an intact pyridine-ribose bond in the β-configuration and a pyridine carboxamide bond at position 3. When NAD is supplied, it is cleaved by extracytoplasmic enzymes to yield NMN or NR, which is taken up and used in the biosynthesis of NAD (Wheat and Pittman, 1960; O'Reilly and Niven, 1986; Cynamon et al., 1988). It appears that none of the members of the family *Pasteurellaceae* are capable of *de novo* synthesis of NAD. V-factor dependency in some species can be explained by their inability to catalyze the formation of the nicotinamide–ribose bond, while all members of the family are incapable of amidating the carbonyl group on a nicotinate residue. Thus, the difference between V-factor dependence and independence within the family is much more subtle (the presence of nicotinamide phosphoribosyltransferase) than hitherto believed (reviewed by Niven and O'Reilly, 1990). Occurrence of V-factor-independent variants of *H. parainfluenzae* from human infections and of poultry isolates of *H. paragallinarum* has been detected in South Africa (Gromkova and Koornhof, 1990; Windsor et al., 1991; Mouahid et al., 1992; Miflin et al., 1995). The property in *H. parainfluenzae* isolates is associated with a 5.25 kb plasmid that can be transferred to *H. influenzae* and confer independence of the V factor (Windsor et al., 1991). Recent studies demonstrate that this plasmid is normally present in strains of *H. ducreyi* (Martin et al., 2001).

The V factor is inactivated by autoclaving and is therefore absent in traditional agar or broth media. Although present in blood, V factor is unavailable in blood agar owing in part to its intracellular location and in part to the presence of NADase in the blood of many species (Krumwiede and Kuttner, 1938). In heated blood agar ("chocolate agar"), in which the blood is added to the basic medium at a temperature of approximately 70°C, the NAD is liberated from the blood cells and the NADase activity destroyed by the high temperature. Traditional sources of V factor, apart from blood, have been yeast derivatives (Thjötta and Avery, 1921), which must be added after autoclaving of the medium. When met by crystalline NAD, V factor requirements of *H. influenzae* were found to range from 0.2–1 μg/ml; those of *H. parainfluenzae*, from 1–5 μg/ml, with some strains requiring as much as 25 μg/ml for optimum growth (Evans et al., 1974).

When inoculated on media deficient in V factor but containing the X factor (e.g., blood agar) *Haemophilus* colonies cluster around contaminant colonies of other bacteria which produce the critical factors in excess (Grassberger, 1897). This phenomenon is called satellitism (Fig. BXII.γ.218) and is sometimes utilized for propagation and characterization of *Haemophilus* spp. It may be demonstrated by inoculating a medium such as blood agar with a strain requiring the V factor. The inoculated area is crossed with a single streak of *Staphylococcus aureus*. Early growth of the *Haemophilus* strain is confined to the area immediately adjacent to the line of staphylococcal growth. It gradually spreads peripherally but remains heaviest in the area nearest the "feeder" streak, reflecting the diffusion gradient of the limiting growth factor. Satellitism on blood agar is strongly suggestive of a V-factor requirement. However, strains of strongly hemolytic strains, particularly *H. parahaemolyticus*, do not show satellitism, due to liberation of ample V factor from the lysed blood cells (Kilian and Poulsen, in preparation). For such strains, the V-factor requirement can be demonstrated on a blood-free agar medium cross-inoculated with *S. aureus* or supplied with a NAD-containing paper disk, or on a medium to which blood is added before autoclaving.

The optimum growth temperature is 35–37°C and the minimum temperature is 20–25°C. Most *Haemophilus* strains are killed by heating at 55°C for 30 min. *H. influenzae* grows better under aerobic than anaerobic conditions. Raised carbon dioxide tension is beneficial, and may be required for surface growth of a number of species, including *H. paragallinarum*, *H. aphrophilus*, *H. paraphrophilus*, and *H. paraphrohaemolyticus*. In the case of *H. paragallinarum* propagated in liquid media, CO_2 has been found to replace a 5% serum requirement observed for some strains under fully aerobic conditions (Rimler et al., 1976; Blackall and Reid, 1982). A serum requirement also exists for *H. parasuis* and *H. ducreyi*. The precise role of serum in these situations is not known. Detoxification of media constituents has been suggested (Page, 1962). Sodium chloride at a concentration of 1–1.5% is essential for the growth of *Haemophilus paragallinarum* (Rimler et al., 1977). Completely synthetic media have been devised re-

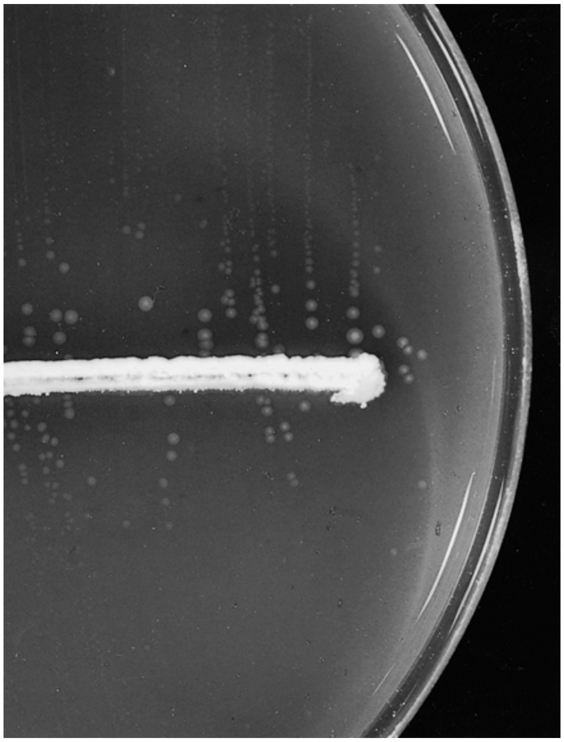

FIGURE BXII.γ.218. Satellitic growth of *H. influenzae* colonies in the vicinity of a streak of *Staphylococcus aureus* that provides the V factor.

peatedly, particularly for *H. influenzae* and *H. parainfluenzae* (Herbst and Snell, 1949; Talmadge and Herriott, 1960; Butler, 1962; Wolin, 1963; Herriott et al., 1970; Klein and Luginbuhl, 1979). In all instances, the adequacy of the medium was tested either with a very limited number of isolates, or was found to support the growth of only a portion of the strains tested. The simplest (Klein and Luginbuhl, 1979) and one of the most complex (Herriott et al., 1970), when tested extensively in parallel, performed exactly alike with regard to their growth-supporting properties.

Metabolism Enzymes of the Embden–Meyerhof–Parnas, hexose monophosphate, Entner–Doudoroff, and tricarboxylic acid cycle pathways have been demonstrated in several *Haemophilus* species (Klein, 1940; White, 1966; Holländer, 1976). Glycolytic growth in the "classical" (White and Sinclair, 1971) sense, however (i.e., in the absence of a functional electron transport chain), has been observed only in X factor-requiring members of the genus, e.g., *H. influenzae*, *H. aegyptius*, and *H. haemoglobinophilus* (White, 1963). In the *H. parainfluenzae* strain studied, glycolysis (as well as oxidative catabolism of glucose) occurred only in the presence of a functional electron transport system and a terminal electron acceptor, viz. oxygen, nitrate, or fumarate (White, 1966; White and Sinclair, 1971). The electron transport chain in the species examined proceeds from flavoproteins (dehydrogenases) via cytochromes *b*, *c*, *d*, and *a* to demethylmenaquinone (DMK) to cytochrome *o* and/or oxygen or nitrate (White and Sinclair, 1971; Holländer, 1976). Strains of *Haemophilus* spp. contain mainly DMK-6 (mean value 78%) with smaller amounts (~10%) of menaquinone-8 (MK-8) and DMK-7. Only *H. aphrophilus* and *H. segnis* lack MK-8. *H. haemoglobinophilus* is unique among the present *Haemophilus* spp. in that it contains exclusively MK-7 (Mutters et al., 1993).

A comprehensive overview of the metabolism of *H. influenzae* as compared with *Escherichia coli* deduced from the genome sequences has been presented by Tatusov et al. (1996).

Genetics *H. influenzae* is the first free-living organism whose genome has been fully sequenced. The 1.83-Mb sequence of the strain Rd (rough variant of a capsular serovar d strain) contains a total of 1743 genes, of which more than 40% have no apparent counterparts of known function in other procaryotes that have been analyzed (Fleischmann et al., 1995). Genetic maps of a strain of *H. parainfluenzae* (genome size 2.34 Mb) and *H. influenzae* serovar b strain Eagan have been constructed by the use of pulsed field gel electrophoresis (Kauc and Goodgal, 1989; Butler and Moxon, 1990). Numerous genes and operons encoding virulence and other properties of *H. influenzae* and other *Haemophilus* species have been cloned and sequenced (available from the National Center for Biotechnology Information).[1]

The genome sizes of *Haemophilus* species range between 1.8 and 2.8 Mb, with *H. influenzae* being the smallest and *H. ducreyi* the largest among species that have humans as their natural habitat (Burbach, 1987). The overall genetic diversity of the genus *Haemophilus*, as revealed by DNA–DNA hybridization studies, is considerable. The most comprehensive strain materials have been examined by Pohl (1979, 1981a) and Burbach (1987), who observed the following binding ratios to DNA of the type species *H. influenzae*: *H. aegyptius*, 70%; *H. haemolyticus* 48–52%; *H. parainfluenzae*, 15–33%; *H. aphrophilus*, 17%; *H. segnis*, 12%; *H. parahaemolyticus*, 14%; *H. paraphrohaemolyticus*, 16%; *H. parasuis* 26%; *H. paracuniculus*, 10%; and *H. haemoglobinophilus*, 22%. Relatively higher binding values, but with the same range, were reported in several other studies. Albritton et al. (1984) and Casin et al. (1986) found more than 90% homology between *H. influenzae* and *H. aegyptius*, whereas the lowest binding ratio (18%) in the study by Albritton et al. (1984) was observed between *H. influenzae* and *H. ducreyi*.

DNA–DNA hybridization studies also have revealed considerable heterogeneity within species. Burbach (1987) found that intra-species homologies among the species subjected to detailed analysis may be as low as 50% within *H. influenzae* and *H. parainfluenzae* and that certain strains of the two species show higher inter-species homology. This problem was solved by creating a new species designated *"H. intermedius"* (see discussion below) (Burbach, 1987).

Available data on 16S rRNA sequences of *Haemophilus* species are presented in Fig. BXII.γ.215. of the chapter on *Pasteurellaceae* by Olsen et al. (this *Manual*). It is notable that relative relationships revealed by DNA–DNA hybridization data are not always reflected in the relationships suggested by the 16S rRNA sequence homologies.

Although many gene sequences from *H. influenzae* reveal mosaic-like patterns and thus evidence of recombination, the population structure of at least encapsulated forms is largely clonal. Multilocus enzyme electrophoresis (MLEE) analysis of over 2000 capsulated *H. influenzae* strains from 30 countries has revealed a limited number of distinct evolutionary lineages, with the major branches corresponding closely to the six capsular serovars (Musser et al., 1990). However, two distinct branches are observed among strains expressing a serovar b capsule. Only one of these branches (division I) contains strains regularly isolated from in-

1. At the time this manual went to press, this information could be accessed at www.ncbi.nlm.nih.gov/htbin-post/Taxonomy/wgetorg?id 12&lvl= 3.

vasive infections, and only 8–9 clones from this branch appear to be responsible for the majority of *H. influenzae* serovar b disease worldwide (Musser et al., 1988, 1990). The population of nonencapsulated *H. influenzae*, which is distinct from that containing capsulated strains, appears to be very large and heterogeneous (Musser et al., 1986; Porras et al., 1986). Whether this significant clonal diversity among non-encapsulated *H. influenzae* is due to more extensive recombination affecting the population structure or merely reflects a larger population size has not been properly analyzed.

Studies of mainly Australian isolates of *H. parasuis* using MLEE analysis also reveal a clonal population structure with two major divisions that partly correlate with serovars (Blackall et al., 1997).

Several mechanisms of horizontal gene transfer have been detected in *Haemophilus* species. Alexander and Leidy (1951) utilized capsulation as a genetic marker to demonstrate the occurrence of transformation in *H. influenzae*. Noncapsulated R variants derived from each of the six capsular serovars a–f were examined for the ability to be transformed by DNA extracted from capsulated donor strains. Strain Rd proved to be the most dependable recipient and could be transformed to capsular types a, b, c, d, e, or f (or combinations of these), according to the capsular type of the DNA donor (Alexander et al., 1954). Catlin and Tartagni (1969) have detected serovar b antigen by immunofluorescence microscopy 40 min after adding transforming DNA to a population of strain Rd. Antibiotic resistance genes located in the chromosome, as well as on small plasmids, have been transferred between *H. influenzae* strains by genetic transformation (Stuy, 1979).

The transformation frequency for *H. influenzae* strain Rd in a rich medium increases from 10^{-7} in early exponential growth phase to about 10^{-4} in late exponential phase. The addition of cAMP to early-phase cultures increases the frequency of transformation to 10^{-4} (Wise et al., 1973; Redfield, 1991). Furthermore, under transient anaerobiosis or transfer to starvation medium, *H. influenzae* transformation frequencies are optimized to approximately 10^{-2} (Herriott et al., 1970). The increased competence under such conditions is paralleled by an altered envelope composition (Zoon and Scocca, 1975). A specific binding protein for homologous double-stranded DNA has been detected in the cell envelope of *H. influenzae* (strain Rd) (Deich and Smith, 1980). This membrane protein recognizes a specific 11-nt sequence that appears with much higher frequency in *Haemophilus* than in other genera (Sisco and Smith, 1979; Danner et al., 1980). Both intra- and interspecific transformation have been demonstrated *in vitro* in several other *Haemophilus* species, and the transformation efficiencies under experimental conditions reflect the overall genetic relationships (Leidy et al., 1956, 1959, 1965; Schaeffer, 1958; Steinhart and Herriott, 1968; Beattie and Setlow, 1970; Albritton et al., 1984).

Screening of *H. influenzae* strain Rd by various random insertional mutagenesis protocols have demonstrated that at least 5 gene loci are required for natural transformation (Larson and Goodgal, 1991; Redfield, 1991; Tomb et al., 1991; Chandler, 1992; Zulty and Barcak, 1995; Gwinn et al., 1997, 1998). Among the identified proteins are the type IV pilin-like protein and a drug-efflux transporter (Dougherty and Smith, 1999).

Plasmids of several sizes have been demonstrated in strains of *H. influenzae* and other *Haemophilus* species. Plasmids coding for resistance to a number of antibiotics have been demonstrated in *H. influenzae*, *H. parainfluenzae*, *H. parahaemolyticus*, and *H. ducreyi*. Two types of R plasmids occur in *H. influenzae*: the large 30–40 MDa conjugative plasmids and the small 2.5–4.4 MDa non-conjugative plasmids (De Graaf et al., 1976; Elwell et al., 1977; van Klingeren et al., 1977; Kaulfers et al., 1978; Laufs et al., 1979; Albritton, 1984). The large self-transferable plasmids carry the complete TnA or Tn10-like transposons in addition to antibiotic resistance genes and are often integrated into the chromosome (Stuy 1980; Levy et al., 1993). They have highly homologous core regions regardless of geographic origin and the antibiotic resistance markers carried (Elwell et al., 1977; Laufs and Kaulfers, 1977), and are closely related to plasmids coding for β-lactamase in *Enterobacteriaceae* (Laufs et al., 1978, 1979). Transfer of large plasmids coding for resistance to one to several antibiotics has been shown among strains of *H. influenzae* and between *H. influenzae* and *Escherichia coli* by a mechanism that requires cell-to-cell contact (Thorne and Farrar, 1975; van Klingeren et al., 1977; Stuy, 1979). The genetic transfer is likely mediated by a conjugation-like process. The same transfer mechanism has been demonstrated in *H. ducreyi* (Brunton et al., 1979; Deneer et al., 1982). Isolates of *H. ducreyi* may contain multiple plasmids of different sizes (1.8, 2.6, 2.8, 3.2, 5.4, 5.7, and 7.0 MDa) (Sarafian et al., 1991; Maclean et al., 1992).

The small R plasmids are highly related to gonococcal plasmids and usually carry only a fraction of the TnA sequence (de Graaf et al., 1976; Laufs et al., 1979). However, two sizes of plasmids (7.0 and 5.7 MDa) encoding β-lactamase with physically complete and functional TnA sequences have been identified in isolates of *H. ducreyi* (Brunton et al., 1982). The complete nucleotide sequence of a small (4.8 kb) yet broad-host-range plasmid encoding resistance to sulfonamides, streptomycin, and kanamycin in *H. ducreyi* has been reported (Dixon et al., 1994). Small cryptic plasmids have been detected in several *Haemophilus* species (Elwell et al., 1977; Stuy, 1979; Albritton et al., 1982b). A small 5.25 kb plasmid has been found to confer independence of V factor in occasional isolates of *H. parainfluenzae* (Windsor et al., 1991) and in *H. ducreyi* (Martin et al., 2001). Plasmids have not been detected in 75 *H. paragallinarum* isolates, including 20 antibiotic-resistant strains (Blackall, 1988), but more recently, a 6 kb plasmid was detected in one isolate (Blackall et al., 1991).

A ~24 kb cryptic plasmid (3031) has been associated with isolates of *H. influenzae* from Brazilian purpuric fever (Brenner et al., 1988a), although not all isolates possess it (Tondella et al., 1995).

Four different bacteriophages of *H. influenzae* have been reported: HP1 (and the mutants cl and c2), HP3, S2, and N3 (Boling et al., 1973; Stuy, 1978). The latter is morphologically distinct, with a longer tail and a contractile sheath. Differences in phage sensitivity and lysogeny have been demonstrated among *H. influenzae* serovars and a number of *Haemophilus* species (Stuy, 1978).

A variety of restriction endonucleases are produced by members of the genus *Haemophilus*. More than 20 different enzymes have been isolated and characterized.

Strains of *H. influenzae* serovar b have been shown to produce a bacteriocin to which other serovars and non-encapsulated *H. influenzae*, *H. parahaemolyticus*, and some strains of *H. parainfluenzae* and *H. haemolyticus* are sensitive (Venezia and Robertson, 1975; Stuy, 1978).

Antigenic structure There is a great deal of antigenic diversity in the genus and even within several species: *H. influenzae* (Pittman, 1931), *H. parasuis* (Bakos, 1955), *H. paragallinarum* (Page, 1962; Kume et al., 1980; Blackall et al., 1990a), *H. paraphrophilus*, and *H. haemoglobinophilus* (Frazer et al., 1975). In spe-

cies in which isolates may possess a capsule, the capsular antigens furnish the basis for serovar specificity. *H. influenzae* isolates that lack a capsule are often referred to as "nontypeable," which is a misnomer that should be substituted by "non-encapsulated." All the capsular antigens studied in sufficient detail have proven to be polysaccharides. They are serologically quite specific, although more than one antigenic determinant may be present in a capsule (Williamson and Zinnemann, 1951, 1954; Branefors-Helander, 1972; Lucas, 1988). Capsular structure and composition have been studied most thoroughly for *H. influenzae*, for which Pittman (1931 and unpublished results) originally described six serologically distinguishable types a–f. The structure of the serovar a–f capsular polysaccharides (and a variant of serovar e, designated e′) is shown in Fig. BXII.γ.219. All six polysaccharides, except those of serovars d and e, contain phosphate and may be characterized as teichoic acids (Crisel et al., 1975; Branefors-Helander, 1977; Branefors-Helander et al., 1979; Egan et al., 1980a, b; Branefors-Helander et al., 1980). Little is known of the physicochemical properties of the capsules of other *Haemophilus* species, apart from *H. parasuis*, in which some, but not all, capsules appear to be composed of an acidic polysaccharide (Morozumi and Nicolet, 1986).

Capsule production in *H. influenzae* depends on a cluster of genes in an 18 kb chromosomal locus termed *cap*, which consists of three major regions. *Cap* region 1 contains four genes (*bex A–D*) necessary for capsular export and, in combination with *cap* region 3, forms the *cap* chassis. *Cap* region 2, located in the middle of the chassis, is the serovar-specific locus, which contains four genes involved in capsule biosynthesis. The *cap* chassis is flanked by the insertion sequence IS1016, forming a compound transposon. In most clinical isolates of *H. influenzae* serovar b (division I isolates), the *cap* locus is composed of multiple (usually two) tandemly repeating *cap* units, and is unique in having a partial deletion of most of the IS1016-*bex A* region, which allows amplification, as well as irreversible loss of capsule expression (Kroll et al., 1993; Roche and Moxon, 1995). As many as 20% of cells in late-exponential liquid cultures of these strains have lost the ability to produce a capsule and will grow on agar medium as small colonies with an irregular surface, containing pleomorphic, often filamentous bacteria with cytoplasmic vacuoles (Roche and Moxon, 1995). A significant proportion of clinical isolates of *H. influenzae* serovar b contain more than 2 copies of the *cap* locus and produce large amounts of capsular polysaccharide (Hoiseth et al., 1992). In contrast, serovar b isolates belonging to phylogenetic division 2 (Musser et al., 1988) have only one copy, like strains of serovars c and d. Serovar a strains have a tandem duplication of intact *cap* loci. PCR-based capsular genotyping has been shown to accurately determine the capsular states of *H. influenzae* isolates, including strains that have lost expression of capsular polysaccharide (Leaves et al., 1995). Occasional clinical isolates of serovar a from Africa have revealed the same deletion in the *cap* locus as found in serovar b isolates. This deletion may be associated with enhanced virulence of some serovar a clones (Kroll et al., 1994). While the majority of noncapsulated *H. influenzae* isolates are not the progeny of capsulate ancestors, some studies have demonstrated isolates that contain *cap*-locus-specific sequences (St. Geme et al., 1994). The reported hybridization of the genome of Brazilian purpuric fever-associated isolates of *H. influenzae* with a *cap* locus probe (Carlone et al., 1989) is, however, due to the presence of IS1016 elements rather than capsule genes (Dobson et al., 1992).

Bacterial antigens cross-reactive with the *H. influenzae* serovar b capsule have been detected across a wide and unrelated variety of bacteria, including *Staphylococcus aureus*, *Staphylococcus epidermidis*, *Streptococcus pyogenes*, *Streptococcus pneumoniae* (serovars 6, 15a, 29, 35a), *E. coli* (K 100), *Lactobacillus plantarum*, *Enterococcus faecium*, *Bacillus alvei*, and *Bacillus pumilus* (Alexander, 1958; Bradshaw et al., 1971; Argaman et al., 1974).

FIGURE BXII.γ.219. Structures of *H. influenzae* capsular polysaccharides. Compiled from data published by Crisel et al., 1975; Branefors-Helander, 1977; Branefors-Helander et al., 1979, 1981; Egan et al., 1980a, b; , Tsui et al., 1981a b; Zon and Robbins, 1983; Byrd et al., 1987. Ribose and fructose are in the furanose ring form. Glc, Gal, GlcNAc, and ManANAc are in the pyranose ring form.

Among somatic antigens, obtained by various extraction procedures and sonic disruption, cross-reactions often occur between serovars within species (Branefors-Helander, 1979; Blackall, 1989) and between species within the genus (Tunevall, 1953; Omland, 1964; Branefors-Helander, 1979; Schiøtz et al., 1979). Among the surface proteins expressed by *H. influenzae* strains, some (P4, P6, lipoprotein D, D15) are immunologically highly conserved, while many others (e.g., P1, P2, P5, pili) show significant antigenic diversity. Antigenic diversity has also been demonstrated for cell wall lipooligosaccharide and the secreted IgA1 protease. The genetic mechanisms creating this diversity include point mutations, phase variation (e.g., alteration of promoter structure and translational frameshift due to slipped strand mispairing), and horizontal gene transfer and homologous recombination (reviewed by Gilsdorf, 1998).

Based on heat-stable somatic antigen extracts, a total of 15 serovars (1 through 15) have been detected among isolates of *H. parasuis* (Kielstein and Rapp-Gabrielson, 1992). Subsequent studies have suggested additional antigenic diversity (Blackall et al., 1997). Several serotyping schemes for *H. paragallinarum* have been reported. The first serological typing system based on whole cell plate agglutination was developed by Page (1962), who recognized three serovars (A, B, and C). This and other similar typing schemes detect several distinct antigens, of which some are common to all members of the species (Blackall, 1989). Other typing systems for *H. paragallinarum* are based on somatic heat-stable antigens and a hemagglutinin (Hinz, 1980; Kume et al., 1983). The Kume scheme, which is based on a heat-labile, trypsin-sensitive hemagglutinin (HA-L), originally recognized three serogroups, termed I, II, and III, and a total of seven serovars, termed HA-1 to HA-7. The serovars are based on minor differences that can be detected with absorbed antisera. Two additional hemagglutin serovars have been described by Blackhall and his coworkers (Eaves et al., 1989; Blackall et al., 1990a), who also proposed a rationalized nomenclature that allows easy addition of new serovars and reconciles the schemes of Page and Kume. Under this altered scheme, the three recognized serogroups I, II, and III are renamed A, C, and B, respectively, and correspond to Page's serovars. Within each of the serogroups, the hemagglutinin serovars are numbered sequentially, allowing new serovars to be added in numerical order. The nine currently recognized serovars are termed A-1, A-2, A-3, A-4, B-1, C-1, C-2, C-3, and C-4 (Blackall et al., 1990a).

Several *H. influenzae* LPS oligosaccharide epitopes are similar to those in pathogenic *Neisseria* species and cross-react with human glycosphingolipid epitopes (Roche and Moxon, 1995). Studies with monoclonal antibodies have demonstrated species-specific epitopes in the LPS of *H. ducreyi* (Borrelli et al. 1995).

Comprehensive proteomic maps of primarily *H. influenzae*, but also including *H. parainfluenzae*, *H. haemolyticus*, and *H. parahaemolyticus*, have been reported by several research groups (Cash et al., 1997; Fountoulakis et al., 1997, 1998a, 1998b).

Antibiotic sensitivity Wild-type strains of the *Haemophilus* species are susceptible to therapeutically achievable concentrations of a wide range of antibiotics. Representative minimum inhibitory concentrations (MICs) of common antibiotics for *H. influenzae* are (μg/ml): benzyl penicillin, 1–2; ampicillin/amoxycillin, 0.5; cefuroxime, 0.5; cefotaxime, 0.06; ceftrioaxone, 0.03; cefaclor, 4; imipenem, 1; chloramphenicol, 0.5; tetracycline, 1; rifampicin, 1; erythromycin, 0.5–8; ciprofloxacin, 0.015; gentamicin, 1; sulfamethoxazole, 4; and trimethoprim, 0.5 (Butt et al., 1997b; Slack and Jordens, 1998).

The macrolide (erythromycin, oleandomycin) and lincosamide antibiotics (lincomycin, clindamycin) are generally less active, and bacitracin has so little effect on *H. influenzae* and other *Haemophilus* species that it is used, in a concentration of 5–19 U/ml, in media for the selective isolation of haemophili (Hovig and Aandahl, 1969; Ederer and Schurr, 1971; see below).

Since 1973, ampicillin resistance among *Haemophilus* species has become an increasing problem. Markedly differing rates of resistance among clinical isolated have been reported in various parts of the world, in some areas exceeding 60% (Campos et al., 1984, 1986). Ampicillin resistance is predominantly due to plasmid-encoded production of β-lactamases, which belong most often to the TEM-1-type, less often to the ROB-1-type, and occasionally to the VAT-1 type (Williams et al., 1974; Elwell et al., 1975; Bell and Plowman, 1980; Markowitz, 1980; Rubin et al., 1981; Maclean et al., 1992; Scriver et al., 1994; Vali et al., 1994; Shanahan et al., 1996). It has been suggested that the ROB-1 β-lactamase has an animal reservoir, as it has been detected in isolates of *Actinobacillus pleuropneumoniae* (Medeiros et al., 1986). Occasional isolates of *H. influenzae* show resistance to the β-lactam agents as a result of alterations in penicillin-binding proteins (Powell, 1988; Mendelman et al., 1990). Plasmid-encoded resistance to other antimicrobics has been observed. These include chloramphenicol (Manten et al., 1976; van Klingeren et al., 1977), tetracycline (Dang Van et al., 1975a; Bryan, 1978), and kanamycin (Dang Van et al., 1975b). Plasmids that simultaneously transfer ampicillin, chloramphenicol, and tetracycline resistance have been found in *H. influenzae* (Bryan, 1978). While tetracycline resistance appears to occur at rates comparable to penicillin–ampicillin resistance in some populations (Piot et al., 1977; Green et al., 1979), chloramphenicol resistance shows significant variation in prevalence (Brotherton et al., 1976; Ward et al., 1978; Butt et al., 1997b; Slack and Jordens, 1998). Resistance to trimethoprim and rifampicin has been observed (Green et al., 1979; Powell et al., 1992; Murphy et al., 1981). Chloramphenicol resistance is almost always due to the production of a plasmid-encoded chloramphenicol acetyl transferase (CAT) type II (Roberts et al., 1980). Non-CAT-mediated resistance is chromosomally encoded and due to a permeability barrier associated with the loss of an outer membrane protein (Burns et al., 1985).

H. parainfluenzae generally shows resistance levels higher than those of nonresistant *H. influenzae* to the antimicrobial agents commonly used on *Haemophilus* species (Kamme, 1969; Mayo and McCarthy, 1977). Both β-lactamase and non-β-lactamase-mediated resistance to ampicillin have been observed in *H. parainfluenzae*, usually at a higher rate than in *H. influenzae* (Green et al., 1979; Kauffman et al., 1979; Walker and Smith, 1980). Transmissible chloramphenicol resistance has been described in *H. parainfluenzae* and credited to CAT-II (Cavanagh et al., 1975; Shaw et al., 1978), while plasmid-encoded aminoglycoside resistance in the same species has been found to be mediated by a phosphotransferase (Le Goffic et al., 1977). Similar observations have been made for isolates of *H. parahaemolyticus* and *H. paraphrophilus* (Jones et al., 1976; Green et al., 1979).

The following minimum inhibitory concentrations (μg/ml) were observed on 19 isolates of *H. ducreyi* (Hammond et al., 1978b): vancomycin, 8–128; polymyxin, 32–128; penicillin G or ampicillin, 4.0 (unless β-lactamase-positive); cloxacillin, 32–64; cephalothin, 4.0–8.0; tetracycline, 0.4–32; doxycycline, 0.25–8.0; chloramphenicol, ≤4.0; rifampin, ≤4.0; sulfisoxazole, ≤8.0; and nalidixic acid, ≤8.0. Plasmid-mediated resistance to sulfonamides, aminoglycosides, tetracyclines, chloramphenicol, and β-

lactam antibiotics have been demonstrated in *H. ducreyi*. It is not unusual for a single *H. ducreyi* isolate to contain multiple resistance plasmids, including more than one plasmid that confers resistance to β-lactam antibiotics (Trees and Morse, 1995).

Resistance to streptomycin is common in strains of *H. paragallinarum*, and strains resistant to tetracycline and sulfonamides also occur. There is no specific knowledge about resistance mechanisms in *H. paragallinarum*. Plasmids are not regularly associated with antibiotic resistance in this species (Blackall, 1988; Blackall et al., 1991).

Pathogenicity Among the *Haemophilus* species that colonize man, *H. influenzae* is clearly the most important from a clinical point of view. Although not responsible for epidemic influenza, as was originally believed, it is involved in a variety of numerically important and severe infections (for review see Turk and May, 1967). These infections can be divided into two groups: (a) acute, pyogenic, and usually invasive infections in which *H. influenzae* (almost exclusively serovar b) is the primary pathogen, and (b) noninvasive infections (often chronic) in which primarily nonencapsulated *H. influenzae* play an important, though in many cases probably a secondary, part.

The acute infections include meningitis in children, of which *H. influenzae* is one of the three leading causes, and other septicemic conditions with local implications, such as epiglottitis, cellulitis, arthritis, and osteomyelitis. More than 95% of *H. influenzae* isolates from these conditions produce a serovar b capsule, and belong to a limited number of clones (Musser et al., 1990), the majority of which are of biovar I (Kilian, 1976; Albritton et al., 1978; Kilian et al., 1979; Oberhofer and Bach, 1979). The introduction in many countries of a conjugated vaccine based on the *H. influenzae* serotype b capsular polysaccharide and one of several protein carriers has virtually eliminated invasive infections due to this serovar (Eskola et al., 1987; Jordens and Slack, 1995; Peltola, 2000). A relatively high prevalence of serovar a isolates have been observed from invasive infection in Papua New Guinea and in White Mountain Apache Indian children (Losonsky et al., 1984; Gratten et al., 1985). Capsulated strains of several serovars may also cause pneumonia. Noncapsulated strains of *H. influenzae* are often implicated in chronic bronchitis, sinusitis, conjunctivitis, and otitis media and have recently been recognized as a major cause of lower respiratory disease in children in the developing world (Foxwell et al., 1998). They occur frequently in the lower respiratory tract of patients with cystic fibrosis during acute exacerbations. Isolates from such conditions are genetically very diverse (Porras et al., 1986; van Alphen et al., 1997), but usually belong to the biovars II and III, the same biovars that colonize the nasopharynx of healthy individuals (Kilian, 1976; Albritton et al., 1978; Oberhofer and Bach, 1979; Granato et al.,1983; Harper and Tilse, 1991). *H. parainfluenzae* biovars identical to those that predominate in the upper respiratory tract are also a relatively frequent finding in respiratory secretions from patients with chronic bronchitis, but their pathogenic role is not clear (Taylor et al., 1992). Occasionally, *H. influenzae* and *H. parainfluenzae* are isolated from genital, pelvic, and urinary tract infections (Quentin et al., 1989; Morgan and Hamilton-Miller, 1990). *H. parahaemolyticus* is rarely isolated from healthy individuals but may be a pathogenic factor in abscesses in the oral cavity and in upper and lower respiratory tract infections (Sims, 1970; Kilian and Poulsen, unpublished studies).

H. aegyptius is a frequent cause of acute and contagious conjunctivitis, mainly in hot climates. Due to difficulties in differentiating *H. aegyptius* from *H. influenzae*, which also causes conjunctivitis, the natural history of *H. aegyptius* infections is poorly understood. There are indications, however, that *H. aegyptius* is associated with a more acute form of conjunctivitis and that the organism, in contrast to *H. influenzae*, can colonize eyes without predisposing conditions being present (see discussion of taxonomic relationship between the two species below). Particular clones of the *H. influenzae*/*H. aegyptius* complex are causing a disease called Brazilian purpuric fever (BPF), which is a fulminant and often fatal infection that starts as conjunctivitis and primarily affects young children. An outbreak of systemic infections due to *H. aegyptius*-like bacteria in sheep in Nigeria has been reported (Akpavie et al., 1994).

H. ducreyi is the causative agent of the venereal disease soft chancre, or chancroid, which is particularly common in Africa, Asia, and Latin America. There has been renewed interest in this pathogen and in chancroid owing to the association between genital ulcers and HIV infection (Trees and Morse, 1995).

H. parainfluenzae, *H. parahaemolyticus*, *H. paraphrohaemolyticus*, *H. segnis*, *H. aphrophilus*, and *H. paraphrophilus*, which occur in the mouth and oropharynx of healthy individuals, are opportunistic pathogens. The oral cavity is usually a likely source of the etiologic agents in infections caused by these organisms. Such infections include endocarditis, brain abscesses, dental abscesses, jaw infections, and infections following human bites or finger sucking (for review, see Frederiksen and Kilian, 1981; Frederiksen, 1993).

The clinical condition of swine in which *H. parasuis* is most frequently encountered is Glässer's disease (polyserositis), a systemic stress-related infection producing fibrinous inflammation of the membranes lining the large body cavities, joints, and meninges. While no antecedent virus infection has been invoked as a precipitant of this condition, stressful events like weaning, weather changes, or movement to new quarters commonly, but not invariably, precede it (for review see Bisgaard, 1993).

H. paragallinarum causes an infection of the upper respiratory tract of chickens called fowl coryza. It begins in the nasal passages and sinuses and spreads to the conjunctivae, and can extend to the air sacs and lungs (Blackall, 1989).

H. haemoglobinophilus is of low pathogenicity. On rare occasions, it has been implicated in urogenital inflammatory disease of dogs. *H. felis* has been isolated from the lower respiratory tract of a cat with chronic obstructive pulmonary disease. Its pathogenic potential probably resembles that of *H. parainfluenzae* in humans (Inzana et al., 1992). *H. paracuniculus* was isolated from the small intestine of rabbits, but its pathogenic potential is unknown (Targowski and Targowski, 1979).

Ecology *Haemophilus* species are obligate parasites and form part of the indigenous flora of the mucous membranes of the human upper respiratory tract, including the oral cavity, and may occasionally be isolated from the vagina and intestinal canal. Humans are the only natural host of the following species: *H. influenzae*, *H. aegyptius*, *H. haemolyticus*, *H. ducreyi*, *H. parainfluenzae*, *H. parahaemolyticus*, *H. paraphrohaemolyticus*, *H. aphrophilus*, *H. paraphrophilus*, and *H. segnis*. *Haemophilus* species constitute approximately 10% of the total bacterial flora in the human upper respiratory tract, and *H. parainfluenzae* accounts for the largest proportion of *Haemophilus* species in the pharynx and oral cavity at all ages. While *H. parainfluenzae* is ubiquitous in the human pharynx and oral cavity, *H. influenzae* is found exclusively behind the palatinal arches (Sims 1970; Kilian and Schiøtt, 1975; Kuklinska and Kilian, 1984; Liljemark et al., 1984). Point prevalence studies of children have shown carriage rates for *H. in-*

fluenzae of 25–84% in the pharynx, although in the absence of local infection, they usually amount to less than 1% of the total microbiota. In contrast to adults, who are less frequently colonized, children often carry multiple clones that show rapid turnover (Kuklinska and Kilian, 1984; Spinola et al., 1986; Trottier et al., 1989; Faden et al., 1995; Smith-Vaughan et al., 1997). Among *H. influenzae* isolates from the upper respiratory tract, only a minority (2–7%) were found by most studies conducted in open communities to be encapsulated. The relative frequencies of the six capsular serovars a–f in such studies were 15, 40, 4, 6, 19, and 15%, respectively (reviewed by Moxon, 1986). Significantly higher nasopharyngeal carriage rates of serovar b strains have been observed among children in institutions such as orphanages and day care centers (Turk and May, 1967). The general vaccination of infants with a conjugate vaccine that includes the serovar b capsular polysaccharide has resulted in a significant reduction of oropharyneal carriage of *H. influenzae* serovar b in some countries (Takala et al., 1991).

H. parainfluenzae is carried by most individuals on the mucosal surfaces of the pharynx and oral cavity, and as members of the biofilm (dental plaque) forming on tooth surfaces. Dynamic colonization patterns similar to those observed for *H. influenzae* have been demonstrated for *H. parainfluenzae* in the pharynx of adults (Kerr et al., 1993). *H. aphrophilus*, *H. paraphrophilus*, and *H. segnis* have a particular predilection for the dental plaque of humans, and the two former species occur primarily in the bacterial deposits between teeth and in deepened gingival crevices in patients with periodontal disease (Kilian and Schiøtt, 1975; Liljemark et al., 1984). *H. haemolyticus* may also be isolated from subgingival dental plaque (Kilian, unpublished observations). The carriage rate of *Haemophilus* species in the anogenital area is approximately 10% or less (Sturm, 1986; Drouet et al., 1989; Martel et al., 1989), although *Haemophilus* spp. have been recovered from over a quarter of stool specimens (Palmer, 1981). Occurrence of *H. ducreyi* in healthy individuals has not been documented.

Haemophilus-like bacteria (V-factor dependent) are also isolated from a variety of mammalian and avian species, including laboratory rodents and rabbits (for review see Grebe and Hinz, 1975; Kilian and Frederiksen, 1981a; Rayan et al., 1987; Nicklas 1989; Busse et al., 1997), but it is questionable whether these belong in the genus *Haemophilus* as presently defined. The only species associated with animals that are still formally (though probably incorrectly) included in the genus *Haemophilus* are *H. parasuis*, *H. paragallinarum*, *H. paracuniculus*, *H. felis*, and *H. haemoglobinophilus*.

H. parasuis has its natural habitats in pigs and is part of the resident microbiota of the upper respiratory tract, mainly in the nasal cavity. The carriage rate may differ between herds (Smart and Miniats, 1989; Møller and Kilian, 1990). Using a selective culture medium, examination of 233 Danish slaughterhouse pigs representing different herds yielded growth of *H. parasuis* from the nasal cavity of 30% of animals (Møller et al., 1993).

H. paragallinarum is found in the respiratory tracts of poultry, but is also an important pathogen (Blackall, 1989p). *H. haemoglobinophilus* is a frequent commensal inhabitant of the lower genital tract of dogs. *H. felis* was isolated from the nasopharynxes of 6 of 28 apparently healthy cats (Inzana et al., 1992).

Enrichment and Isolation Procedures

The traditional way of demonstrating *Haemophilus* organism in samples from mucosal membranes is to inoculate a blood agar plate and cross-inoculate it with a *Staphylococcus* strain to provide the V factor. Most *Haemophilus* species will grow to sizeable colonies in the vicinity of the feeder strain after overnight incubation at 35–37°C in air supplemented with 5–10% extra CO_2. However, in mixed cultures haemophili may easily be overgrown. Thus, respiratory samples often give rise to heavy growth of haemophili on selective media in cases where no apparent *Haemophilus* colonies are detectable by routine cultivation methods.

Chocolate agar supplemented with 100–300 μg/ml (6.3–18.9 U/ml) of bacitracin is a very satisfactory medium for the selective isolation of species of *Haemophilus* (Hovig and Aandahl, 1969; Ederer and Schurr, 1971). Some pharyngeal and oral *Neisseria* species grow on this medium, as do *Actinobacillus actinomycetemcomitans* and *Eikenella corrodens*. An alternative selective medium that gives equally satisfactory results is chocolate agar supplemented with bacitracin (5 U/ml) and cloxacillin (5 μg/ml) (Sims, 1970). A selective agar medium that allows differentiation of *H. influenzae* and *H. parainfluenzae* (and other V-factor dependent species) based on the detection of sucrose fermentation by the latter has been described by Roberts et al. (1987) and in modified form by Taylor et al. (1990).

For the more fastidious haemophili (e.g., *H. ducreyi* and *H. aegyptius*), higher isolation rates are obtained with chocolate agar enriched with 1% IsovitaleX (BBL) (Hammond et al., 1978a; Vastine, et al., 1974). GC-HgS agar consisting of GC agar (GIBCO Laboratories) supplemented with 3 mg of vancomycin per liter, 1% hemoglobin, 5% fetal bovine serum, 1% IsoVitaleX (BD Diagnostics) or other comparable enrichment has a high sensitivity for isolation of *H. ducreyi* from clinical specimens; so has MH-HB agar, i.e., Mueller–Hinton agar (BBL) supplemented with 5% chocolatized horse blood, 1% IsoVitaleX, and 3 mg/l of vancomycin. It is generally accepted that a combination of two media, e.g. GC-HgS and MH-HB, is optimum for the isolation of *H. ducreyi*, possibly because of differences in nutritional requirements between strains, but the sensitivity for *H. ducreyi* is never 100%. Some lots of fetal calf serum inhibit growth of *H. ducreyi*. Fetal calf serum can be replaced by either activated charcoal or bovine albumin, but not by newborn calf serum (for a review see Trees and Morse, 1995). Some strains of *H. paragallinarum* require chicken serum for growth, while other strains simply show improved growth in its presence (Hinz, 1973; Blackall and Reid, 1982). Sodium chloride at a concentration of 1.0–1.5% is essential for the growth of *H. paragallinarum* (Rimler et al., 1977).

Maintenance Procedures

Plate and tube cultures of haemophili usually survive no longer than 1 week without subcultivation. Survival is often better at room temperature than at 4°C. The most satisfactory way of conserving cultures is by lyophilization, e.g., in skim milk. Levinthal broth cultures remain viable for at least 2 years when frozen at −70°C in sealed glass ampules.

Procedures for Testing Special Characters

Test for porphyrin synthesis (X-factor requirement) Like many other bacteria, hemin-independent *Haemophilus* strains excrete porphobilinogen (PBG) and porphyrins, intermediates in the hemin biosynthetic pathway (Fig. BXII.γ.217), when supplied with δ-aminolevulinic acid (ALA). In contrast, hemin-requiring strains do not excrete these compounds because they lack the enzymes responsible for their synthesis (Biberstein et al., 1963). This is the rationale for the porphyrin test, which is the easiest and most reliable means of determining X-factor requirement in *Haemophilus* organisms (Kilian, 1974).

A substrate of the following composition is used: δ-aminolevulinic acid, (Sigma), 2 mM; and $MgSO_4$, 0.08 mM; in 0.1 M phosphate buffer, pH 6.9. The substrate is distributed in 0.5-ml quantities in small glass tubes and is inoculated with a heavy loopful of bacteria from an agar plate culture. After incubation for 4 h at 37°C, the result is read under Wood's light (360 nm), preferably in a dark room. A red fluorescence from the bacterial cells and/or the fluid is indicative of porphyrins (Fig. BXII.γ.217), meaning that the strain is independent of the X factor.

An alternative method of reading is to add 0.5 ml of Kovacs' reagent, shake vigorously, and allow the phases to separate. A red color in the lower water phase, indicative of porphobilinogen (Fig. BXII.γ.217), means that the strain is independent of X factor. With this method of reading, an inoculated "substrate" without ALA must be included to avoid false positive reactions due to indole, which also gives a red color with Kovacs' reagent (Fig. BXII.γ.217).

The traditional use of paper disks impregnated with X factor on agar media cannot be recommended for the demonstration of an X-factor requirement. Even with care, use of this method results in misidentifications approaching 20% (M. Kilian and K.R. Eriksen, unpublished results). Such misidentifications undoubtedly account for most of the reported isolates of *H. parainfluenzae* from invasive infections.

V-factor requirement The satellite phenomenon mentioned above is widely used as a means of determining V-factor requirement. This phenomenon may be demonstrated on an agar medium lacking the V factor by cross-inoculating the plate with an appropriate feeder strain (e.g., *Staphylococcus* or *Pseudomonas*). More unequivocal results may be obtained by the application of a V-factor-impregnated paper disk. Media in which all ingredients have been autoclaved are consistently free of V factor, whereas ordinary blood agar contains varying amounts of available V factor. A convincing satellite phenomenon is, therefore, sometimes difficult to achieve on ordinary blood agar plates, particularly with strains of hemolytic species. The best results are obtained on a blood agar medium in which the blood (5–10%) has been added before autoclaving. This medium is completely devoid of V factor but otherwise satisfies all growth requirements of the *Haemophilus* species, including the X factor.

Fermentation of carbohydrates Fermentation of carbohydrates can be studied in phenol red broth base (Difco) supplemented with 1% of the respective carbohydrates and 10 mg/l each of NAD and hemin, the former added as a solution sterilized by filtration (Kilian, 1976). In this medium, most strains of *H. parainfluenzae*, *H. parahaemolyticus*, *H. aphrophilus*, *H. paraphrophilus*, and *H. haemolyticus* release hydrogen and CO_2 during fermentation of glucose (Kilian, 1976). This activity may be demonstrated by inserting an inverted Durham tube in the glucose broth. *H. paracuniculus* is reported to be unable to grow in phenol red broth base supplemented with V factor. Purple broth base supplemented with NAD (10 mg/l) is recommended for the examination of fermentation reactions in this organism (Targowski and Targowski, 1979).

Hemagglutination The hemagglutinating activity found in most fresh isolates of *H. influenzae* and *H. aegyptius*, and in some isolates from fowl and swine is demonstrated as described by Davis et al. (1950). The property is easily lost upon subcultivation of isolates.

Typing of capsules Commercial antisera are available for the differentiation of the six capsular serovars of *H. influenzae*, and several techniques may be applied. Slide agglutination is the traditional method and gives reliable results when performed with care. It is wise to consider as positive only those agglutinations that occur within a few seconds. Delayed reactions should be interpreted very cautiously, as commercial antisera also contain antibodies against somatic antigens. Although more time-consuming, the use of the Quellung reaction greatly strengthens the reliability of typing. An alternative serological method that gives reliable results is coagglutination using commercial reagents (Himmelreich et al., 1985). Typing may also be achieved by demonstration of serovar-specific gene sequences. A probe (pUO38) that recognizes the cap region of all six serovars reveals 14 distinct banding patterns in *Eco*RI-digested chromosomal DNA, which can be directly translated into serovars (Kroll et al., 1991). Capsular typing by PCR is another method that accurately determines the capsular states of *H. influenzae* isolates, including b^- strains. It is easier to perform than probe analysis, as there is no need for DNA extractions, Southern blotting, and hybridization. The method furthermore recognizes four cap b patterns not detected by pUO38 hybridization (Leaves et al., 1995). Details about probes and primers are provided by Herbert et al. (1998).

Micromethods for Examination of *Haemophilus* Strains Micromethods that do not require growth are recommended for the detection of indole production, urease, ornithine, and lysine decarboxylases, and arginine dihydrolase and for the demonstration of glycosidase activities. All these tests use 0.5-ml quantities of the substrate and are inoculated by suspension of a heavy loopful of bacteria in the substrate. The results can usually be read after incubation for 4 h at 37°C, but the incubation may be extended to 24 h.

Indole test The substrate is 0.1% L-tryptophan in 0.067 M phosphate buffer at pH 6.8. After incubation, 0.5 ml of Kovacs' reagent is added and the mixture shaken. A red color in the upper alcohol phase indicates the presence of indole (Clark and Cowan, 1952).

Urease test The basal medium consists of (per 100 ml of distilled water): KH_2PO_4, 0.1 g; K_2HPO_4, 0.1 g; NaCl, 0.5 g; and phenol red solution (1:500, prepared by dissolving 0.2 g in 92 ml distilled water + 8 ml 1 N NaOH), 0.5 ml. pH is adjusted to 7.0 with 5 N NaOH, autoclave, and add 10.4 ml of urea solution (20% aqueous, sterilized by filtration). A red color that develops within 4 h after inoculation indicates urease activity (Lautrop and Lacy, 1960).

Amino acid decarboxylases Ornithine and lysine decarboxylases and arginine dihydrolase can be demonstrated in Møller's medium (Møller, 1955). When this is heavily inoculated with positive strains, a purple color develops within 4 h.

Glycosidases Glycosidase activities can be demonstrated in 0.1% buffered solutions (w/v) of the respective chromogenic nitrophenol derivatives (Kilian, 1978). A yellow color developing within 4 h indicates glycosidase activity.

Most of the biochemical tests mentioned above can be performed with commercial micromethod kits, such as API 10E, API 20E, HNID (Quentin et al., 1992), the Minitek System (BBL) (Oberhofer and Bach, 1979), API NH (Barbé et al., 1994), Rapid NH and RIM-*Haemophilus* (Barbé et al., 1994).

Differentiation of the genus *Haemophilus* from other genera

According to the definition of the genus employed in the previous edition of this *Manual*, the demonstrable need of X or V factor on the part of a Gram-negative rod or coccobacillus would qualify that organism as a *Haemophilus* strain. Conversely, the absence of such need would exclude a bacterium from the genus (Kilian and Biberstein, 1984). However, in the intervening period several V-factor-dependent species have been transferred from the genus *Haemophilus* to other genera within and outside the family *Pasteurellaceae* based on genetic data. *"H. pleuropneumoniae"* has been transferred to the genus *Actinobacillus* (Pohl et al., 1983). *"Haemophilus avium"*, which turned out to be a heterogeneous taxon, has been transferred to the genus *Pasteurella* as *P. avium*, *P. volantium*, and an additional, yet unnamed, taxon designated *Pasteurella* species A (Mutters et al., 1985b; Piechulla et al., 1985b). Finally, *"H. equigenitalis"* has been reclassified as *Taylorella equigenitalis* (Sugimoto et al., 1983).

As a result of the reclassification of these species, V-factor requirement is now a property of some species of both *Actinobacillus* and *Pasteurella*. In addition, three V-factor-dependent taxa of porcine origin have been proposed as new species within the genus *Actinobacillus*, i.e., *A. minor* (formerly *Haemophilus* taxon "minor group" of Kilian et al., 1978), *A. porcinus*, and *A. indolicus* (Møller et al., 1996a). Conversely, it has become clear that some of the remaining *Haemophilus* species (i.e., *H. parainfluenzae* and *H. paragallinarum*) may include occasional members that are independent of the V factor, at least in some cases as a result of a transferable plasmid (see above). Similarly, as discussed above, isolates of *H. aphrophilus* often lack a demonstrable requirement for X factor, and the apparent requirement in fresh isolates is not due to a lack of enzymes in the biosynthetic pathway of heme as in *H. influenzae*. As a result, the previous definition of the genus is no longer valid.

Despite the reallocation of some species, the definition of the genus *Haemophilus* and the delineation of the individual genera in the family *Pasteurellaceae* have not become any clearer. As discussed by Olsen et al. in the chapter describing the family *Pasteurellaceae* (this *Manual*), available data suggest that it will be difficult to divide the family *Pasteurellaceae* into genera that are phenotypically and phylogenetically coherent. However, there is no doubt that several of the species currently assigned to the genus *Haemophilus* belong elsewhere. Based primarily on DNA–DNA hybridization data of Burbach (1987), Mutters et al. (1989) have proposed restricting the genus *Haemophilus sensu stricto* to *H. influenzae*, *H. aegyptius*, *H. haemolyticus*, *"H. intermedius"*, and *H. parainfluenzae*. In contrast, phylogenetic analyses by 16S rRNA sequence comparisons suggest that the genus should instead be restricted to *H. influenzae*, *H. aegyptius*, *H. haemolyticus*, and *"H. intermedius"*; whereas *H. parainfluenzae* is only distantly related. *H. aphrophilus*, *H. paraphrophilus*, and *H. segnis* belong to a separate cluster related to *Actinobacillus actinomycetemcomitans* (see Fig BXII.γ.215 of Olsen et al. in the chapter describing the family *Pasteurellaceae*, this *Manual*).

Allocation of isolates to one of the existing species of *Haemophilus* usually presents no problems. This can be achieved in the clinical microbiological laboratory by examination of phenotypic traits or, if sequencing facilities are available, by partial sequencing of 16S rRNA genes. However, a decision concerning the correct allocation of newly discovered taxa to any one of the existing genera within *Pasteurellaceae* is problematic. There are at present no phenotypic traits known that correlate with the 16S rRNA sequence homology data and that would provide a workable basis for reconciling the genetic information with the practical needs for laboratory identification of genera and species. Thus, at present, the decision would be made based on genetic data, in particular, comparison of 16S rDNA sequences of an unknown isolate with available sequences for the respective type species, but even then the most natural allocation would not necessarily be clear-cut.

Of all the secondary criteria usually cited as characteristic of the genus, such as carbohydrate fermentation, alkaline phosphatase activity, and nitrate reduction, only the lattermost is without exception among the currently recognized species, and none are exclusive. Other chemotaxonomic criteria are discussed by Olsen, et al. (see the chapter on the family *Pasteurellaceae*, this *Manual*). There are no motile members of the genus, and the question of whether motility would exclude an organism meeting the other standards of the genus has never arisen.

Organisms with growth factor requirements comparable to those of *Haemophilus* spp. occur sporadically among other, unrelated taxa (Jensen and Thofern, 1953; Beljanski, 1955; Caldwell et al., 1965). The basis for excluding them from the genus *Haemophilus* is, in addition to genetic data such as significant differences from *H. influenzae* in 16S rRNA genes, based on morphological, tinctorial, and cultural characteristics identifying them with their parent taxa.

Taxonomic Comments

In addition to the described problems related to the definition of the genus, several other taxonomic problems remain to be solved in the genus *Haemophilus*. These problems include species that seem to belong not in the genus, but rather elsewhere in the family *Pasteurellaceae*, as well as problems related to some of the "true" *Haemophilus* species. According to phylogenetic analyses based on 16S rDNA sequence comparisons, the species *H. ducreyi*, *H. parainfluenzae*, *H. parahaemolyticus*, *H. paraphrohaemolyticus*, *H. haemoglobinophilus*, *H. parasuis*, *H. paragallinarum*, *H. paracuniculus*, and *H. felis* do not cluster with the type species *H. influenzae* and seem to be misplaced in the genus *Haemophilus* (see Fig BXII.γ.215 of Olsen et al. in the chapter on the family *Pasteurellaceae*, this *Manual*).

The taxonomic position of *H. ducreyi* has been questioned for a number of years in spite of its requirement for X factor and a mol% G + C content of DNA within the accepted range for *Haemophilus* species. DNA hybridization data indicate that *H. ducreyi* is unrelated to *H. influenzae* (Casin et al., 1985). Sequence comparisons of 16S rDNA of selected isolates of *H. ducreyi*, including the type strain (CIP542), with representatives of a large number of species support its exclusion from the genus *Haemophilus* but confirm that it belongs in the family *Pasteurellaceae* (Dewhirst et al., 1992).

H. parainfluenzae is a genetically very diverse species. Although Mutters et al. (1993) included it in *Haemophilus sensu stricto*, 16S rRNA sequence data of a limited number of strains reveal that it is phylogenetically only distantly related to *H. influenzae* and belongs elsewhere in the family *Pasteurellaceae*. Further studies of a larger number of representative strains reflecting the diversity of the species are required to establish the natural affiliation of this species. Likewise, *H. parahaemolyticus* clusters with *A. lignieresii*, but the 16S rRNA sequence on which this position is based appears to be incorrect (Hedegaard et al., 2001). *H. parasuis* clusters with *Actinobacillus indolicus*; *H. paracuniculus*, with *Acti-*

nobacillus capsulatus; and *H. paragallinarum*, with a cluster of avian species including *Pasteurella gallinarum* (see discussion of the family *Pasteurellaceae* by Olsen et al. in the chapter on the family *Pasteurellaceae* in this *Manual*). Solutions to these problems must await clarification of the overall taxonomic structure of the family *Pasteurellaceae*. The fact that results of DNA reassociation and 16S rRNA sequencing are in some cases in conflict emphasizes the need for more comprehensive genetic approaches.

Numerous taxonomic questions need to be solved, even within the genus *Haemophilus sensu stricto*. Several of these problems are associated with *H. influenzae* and its close relative *H. aegyptius*. Based on cluster analyses of comprehensive DNA–DNA reassociation data, Burbach (1987) recognized two subgroupings within *H. influenzae* and proposed them as subspecies, designated *"H. influenzae* subsp. *influenzae"* and *"H. influenzae* subsp. *meningitidis"*, respectively. *"H. influenzae* subsp. *influenzae*" includes the type and consists of noncapsular strains and encapsulated strains of serovars a, c, and f, all belonging to biovars II, III, and VII. *"H. influenzae* subsp. *meningitidis"* includes encapsulated strains of serovars a, b, d, and e, as well as noncapsular strains. Biovars I, II, IV, and V are represented among these strains. Excepting a single biovar II strain included in " subsp. *meningitidis"*, a positive ornithine decarboxylase test can distinguish " subsp. *meningitidis"* from *"H. influenzae* subsp. *influenzae*". However, with regard to serovars and biovars, these subgroups are not consistent with those observed by cluster analysis of multilocus enzyme electrophoresis data (Musser et al., 1986, 1988).

Among strains previously identified as *H. influenzae*, Burbach (1987) furthermore observed a distinct cluster of three strains with biochemical properties as described for biovar VIII (Sottnek and Albritton, 1984). The cluster is only distantly related to *H. influenzae* but is close to *H. haemolyticus*. The designation "*H. intermedius* subsp. *gazogenes*" was applied to this taxon, as the strains produce gas in glucose broth. Three other strains previously identified as *H. parainfluenzae* biovars III and IV are closely related to "*H. intermedius* subsp. *gazogenes*", in spite of differences in X-factor requirement, and these were designated "*H. intermedius* subsp. *intermedius*". Analysis of 16S rRNA sequences of two representative strains confirm that these taxa are distinct from *H. influenzae* and *H. parainfluenzae*, respectively, and are closely related to *H. haemolyticus* (see Fig BXII.γ.215. of Olsen et al. in the chapter on the family *Pasteurellaceae*, this *Manual*). However, the species *"H. intermedius"* has not been formally validly named and, phenotypically, appears difficult to handle in practice.

Studies from North America and France have revealed a relatively high prevalence of noncapsular *H. influenzae* biovar IV among isolates from cases of neonatal bacteremia and meningitis and obstetric infections (Albritton et al., 1982a; Wallace et al., 1983; Quentin et al., 1990). Phylogenetic analyses performed by multilocus enzyme electrophoresis, DNA–DNA hybridization, and rRNA gene polymorphism strongly suggest that such strains form a separate species related to *H. influenzae*, *H. aegyptius*, and *H. haemolyticus* (Quentin et al., 1990, 1993, 1996). It is not clear if all isolates with the characteristics of biovar IV belong in this taxon. This taxon is provisionally referred to as *"Haemophilus quentini"* in Fig. BXII.γ.215 of Olsen et al. (see chapter on the family *Pasteurellaceae*, this *Manual*).

Several studies have addressed the relationship between *H. influenzae* and *H. aegyptius* and the question of whether both deserve specific recognition. Phenotypically, *H. aegyptius* is similar, but not identical to *H. influenzae* (Mazloum et al., 1982). In the three biochemical tests used to distinguish the biovars of *H. influenzae*, *H. aegyptius* is identical to biovar III (Kilian, 1976; Mazloum et al., 1982), for which reason many researchers have identified all conjunctival isolates with those characteristics as *H. aegyptius*. This may explain some of the conflicting results that have been published on the degree of phenotypic relatedness of the two taxa. Clearly, "true" *H. influenzae* (biovars II and III) are frequently also isolated from cases of conjunctivitis in temperate climates (Kilian et al., 1976). DNA–DNA hybridization data, transformation experiments, and 16S rRNA sequence comparisons all confirm that the two species are closely related (Leidy et al., 1959; Leidy et al., 1965; Pohl, 1981a; Albritton et al., 1984; Casin et al., 1986; Burbach, 1987). While Casin et al. (1986) concluded that the two taxa are indistinguishable, Burbach (1987) found that *H. aegyptius* strains form a distinct entity. The latter conclusion is supported by phenotypic differences and by studies of outer membrane profiles, which have revealed a distinct pattern in strains of *H. aegyptius* (Carlone et al., 1985). Although these differences indicate that *H. aegyptius* is a distinct subpopulation, they do not necessarily show that both *H. influenzae* and *H. aegyptius* warrant status as separate species.

Based on their DNA reassociation data, Casin et al. (1986) argued that *H. aegyptius* be considered a junior subjective synonym of *H. influenzae*. However, this is incorrect. While *H. influenzae* is the type species, the epithet *aegyptius* Trevisan 1889b has formal priority over the epithet *influenzae* Lehmann and Neumann 1896. "To avoid confusion" Brenner and coworkers (1988a) used the informal designation "*H. influenzae* biovar aegyptius" to denote strains formerly called *H. aegyptius*. The term was also applied to isolates from the disease Brazilian purpuric fever (BPF) and subsequently has been used frequently in the literature on this pathogen. Most isolates from the original outbreak and subsequent cases of BPF in Brazil belong to at least three different clones ("BPF clones"), although minor differences in ribotype and plasmid content have been observed within clones. Isolates from occasional cases in Australia are not closely related to the Brazilian clone (Musser and Selander, 1990). The Brazilian BPF clone fails to ferment D-xylose (Brenner et al., 1988a), like strains of *H. aegyptius* and occasional strains of *H. influenzae* (Mazloum et al., 1982). Recent phylogenetic and other analyses demonstrate that BPF clone isolates and *H. aegyptius* are two recently diverged but distinct populations that are separate from *H. influenzae* (Kilian, Poulsen, and Lomholt, unpublished). Thus, the specific status and nomenclature of the two present taxa *H. influenzae* and *H. aegyptius* remain an unsolved problem.

Collectively, the observations described above emphasize that there is a need for comprehensive population genetic analyses of *H. influenzae* and *H. parainfluenzae* strains that fully reflect the genetic diversity within these species in order to clearly define them, as well as neighboring species.

The two species *H. aphrophilus* and *H. paraphrophilus* are differentiated by the requirement for V factor by the latter (Table BXII.γ.294). *H. aphrophilus* has an apparent X-factor requirement when freshly isolated, but contains all the enzymes of the heme biosynthetic pathway (White and Granick, 1963). On subculture, variant colonies consisting of X factor-independent cells arise and apparently supplant the original population (Boyce et al., 1969). Strains carried by type culture collections usually do not have the X-factor requirement. In practice, *H. aphrophilus* is identified by criteria other than the growth factor requirement. Numerous genetic and chemotaxonomic analyses have been applied to strains of the two species to clarify their taxonomic relationship. Results of DNA–DNA hybridization, genetic transformation

(Pohl., 1981a; Tanner et al., 1982; Potts et al., 1985; Tønjum et al., 1990), 16S rRNA sequencing (Dewhirst et al., 1992), ribotyping (Sedlácek et al., 1993), multilocus enzyme electrophoresis (Caugant et al., 1990), and whole cell protein mapping by two-dimensional gel electrophoresis (Olsen et al., 1987) fail to identify two separate groups. In contrast, according to Brondz and Olsen (1990) and Myhrvold et al. (1992), multivariate statistical analyses of LPS carbohydrates and enzyme data support their recognition as separate taxa. No formal action has so far been taken, and the two species are maintained as separate species in this chapter.

A proposal was made (Potts et al., 1985) to transfer the species *Actinobacillus actinomycetemcomitans*, which is associated with periodontal disease in humans, to the genus *Haemophilus*, based on its close genetic relationship to *H. aphrophilus* (Tanner et al., 1982; Potts et al., 1985). However, due to the rather distant relationship with the type species *H. influenzae*, as judged by DNA reassociation studies, this proposal has not been generally supported. Comprehensive phylogenetic analyses based on 16S rDNA sequence comparisons reveal that the species clusters neither with *H. influenzae* nor with *Actinobacillus lignieresii* but do confirm its close association with *H. aphrophilus*, *H. paraphrophilus*, and *H. segnis* (see Fig. BXII.γ.215 of Olsen et al. in the chapter on the family *Pasteurellaceae*, this *Manual*).

The previous edition of *Bergey's Manual of Systematic Bacteriology* listed three taxa as *species incertae sedis* under the genus *Haemophilus*: *"Haemophilus somnus"*, *"Haemophilus agni"*, and *"Haemophilus equigenitalis"* (Kilian and Biberstein, 1984). The lattermost was subsequently transferred to a new genus *Taylorella* (Sugimoto et al., 1983). *"Haemophilus somnus"*, which is associated with cattle as both a commensal and a recognized pathogen, and the phenotypically and genetically related *"Haemophilus agni"* are not genetically related to the genus *Haemophilus*, as demonstrated by DNA–DNA hybridization (Piechulla et al., 1986), DNA–rRNA hybridization (de Ley et al., 1990), and the degree of 16S rRNA sequence homology (Dewhirst et al., 1993). They may represent a new genus within the family *Pasteurellaceae* (Bisgaard, 1995). De Ley et al., (1990) suggested that both be transferred to genus *"Histophilus"*, *"Histophilus ovis"* being a senior synonym for *"Haemophilus agni"*. However, none of these names are valid, and no types have been designated. As the taxa are still often referred to as *"Haemophilus somnus"* and *"Haemophilus agni"*, the descriptions are maintained here under Other Organisms.

Acknowledgments

In the previous edition of this *Manual*, the chapter on the genus *Haemophilus* was co-authored with Dr. E.L. Biberstein. I am grateful for his many contributions and for what remains in this version.

Differentiation of the species of the genus *Haemophilus*

The differential characteristics of the species of *Haemophilus* are presented in Table BXII.γ.294. Other characteristics of the species are presented in Table BXII.γ.295.

List of species of the genus Haemophilus

1. **Haemophilus influenzae** (Lehmann and Neumann 1896) Winslow, Broadhurst, Buchanan, Krumwiede, Rogers and Smith 1917, 561^{AL} (*Bacterium influenzae* Lehmann and Neumann 1896, 187.)

in.flu.en'zae. Italian n. *influenza* influenza; M.L. gen. n. *influenzae* of influenza.

Coccobacilli or small regular rods 0.3–0.5 × 0.5–3.0 μm. Colonies on chocolate agar are smooth, low, convex, grayish, and translucent and attain a diameter of 0.5–1.0 mm in 24 h. Capsulated strains usually produce larger and more mucoid colonies (1–3 mm), which show a tendency to coalesce with no visible line of demarcation. On transparent agar media, colonies of capsulated strains show iridescence when examined under obliquely transmitted light.

Among encapsulated isolates, six serovars (a-f) have been identified (Pittman, 1931; M. Pittman, unpublished results). The structure of the serovar a–f capsular polysaccharides is shown in Fig. BXII.γ.219. A total of 41 capsular and somatic antigenic determinants have been detected in a strain of *H. influenzae* serovar b by crossed immunoelectrophoresis. A considerable number of these determinants are related to antigenic determinants of strains of *H. haemolyticus*, *H. parainfluenzae*, and various enterobacteria (Schiøtz et al., 1979).

H. influenzae strains may be assigned to any of seven biovars (I-VII) based on three biochemical characteristics, indole production, and urease and ornithine decarboxylase activities (Tables BXII.γ.294 and BXII.γ.296) (Kilian, 1976; Oberhofer and Bach, 1979; Gratten 1983). Strains described as *H. influenzae* biovar VIII (Sottnek and Albritton, 1984) were subsequently shown to be distinct from *H. influenzae* and were assigned to the not validly published taxon "*H. intermedius* subsp. *gazogenes*" (see above). The majority of strains with a serovar b capsule are of biovar I, an observation that first suggested that serovar b strains are distinct from non-capsulated strains, most of which belong to biovars II and III. All isolates so far examined with a serovar d and e capsule are of biovar IV (Kilian, 1976).

H. influenzae possesses neuraminidase activity (Müller and Hinz, 1977). Virtually all strains produce an extracellular endopeptidase (IgA1 protease) capable of inducing specific cleavage of a proline–serine or a proline–threonine peptide bond in the hinge region of human immunoglobulin A1 (Kilian et al. 1996).

H. influenzae is present in the nasopharynxes of a majority of healthy children. The carriage rate in adults is somewhat lower (Kilian and Frederiksen, 1981a). It is rarely encountered in the human oral cavity and has not been

detected in any animal species apart from chimpanzees. Capsulated strains are harbored intermittently in the nasopharynx of a minority of healthy individuals (3–7%). Serovars b and f are the serovars most frequently encountered, whereas serovar c strains are rare (Moxon, 1986).

H. influenzae was isolated originally from cases of endemic influenza and was regarded as its causative agent at the time. It is frequently isolated from chronic infections of the upper and lower human respiratory tract, paranasal sinuses, middle ears, and conjunctivae, in which conditions *H. influenzae* plays an important, though often probably a secondary, part. Strains implicated in such conditions are usually noncapsulated and belong to the biovars II or III like the majority of isolates from healthy upper respiratory tracts (Kilian and Frederiksen, 1981a). Encapsulated strains of serovar b are among the three most common causes of bacterial meningitis in children and occasionally cause acute epiglottitis (obstructive laryngitis) cellulitis, osteomyelitis, and joint infections (Turk and May, 1967).

The mol% G + C of the DNA is: 39 (T_m).

Type strain: 680 of Pittman (noncapsulated, biovar II) ATCC 33391, NCTC 8143.

GenBank accession number (16S rRNA): M35019.

Additional Remarks: Reference strains: NCTC 8466 (serovar a, biovar I); NCTC 7279 (serovar b, biovar I); NCTC 8469 (serovar c, biovar II); NCTC 8470 (serovar d, biovar IV); NCTC 10479 (serovar e, biovar IV); NCTC 8473 (serovar f, biovar I); NCTC 4560 (noncapsulated, biovar III); NCTC 11394 (noncapsulated, biovar V).

2. **Haemophilus aegyptius** (Trevisan 1889b) Pittman and Davis 1950, 413[AL] (*Bacillus aegyptius* Trevisan 1889b, 13.)
ae.gyp′ ti.us. L. adj. *aegyptius* Aegyptian.

The common name of the organism is Koch–Weeks bacillus. Long slender rods 0.2–0.3 × 2.0–3.0 µm. Growth of freshly isolated strains on chocolate agar is slow. After 48 h, colonies attain a diameter of about 0.5 mm and are smooth, low, convex, grayish, and translucent. The species does not grow on Tryptic soy agar (Difco) with X and V factors added, in contrast to *H. influenzae*. Forms comet-like colonies in semisolid agar media (Pittman and Davis, 1950).

Capsules have not been demonstrated. Bacteria of this species produce an extracellular IgAl-cleaving endopeptidase (Lomholt and Kilian, 1995; Kilian et al., 1996) and have neuraminidase activity (Müller and Hinz, 1977).

Features which may be of use in distinguishing *H. aegyptius* from *H. influenzae* include poorer growth on most media, a lack of indole production, and D-xylose fermentation, the distinct bacillary morphology, a hemagglutinating activity, the comet-like growth in semisolid media, and the susceptibility to troleandomycin. However, none of these features unequivocally differentiate the two species.

Some strains lack the enzyme ferrochelatase, which inserts iron into protoporphyrin IX, and thus require protoheme as X-factor (White and Granick, 1963; Kilian et al., 1976; Ruckelshausen and Holländer, 1978). The organism causes acute or subacute infectious conjunctivitis in hot climates. It has not been demonstrated in healthy individuals. Particular clones ("BPF clones") closely related to *H. aegyptius* have been associated with Brazilian purpuric fever. The clones have been referred to as *H. influenzae* biogroup *aegyptius* (see comments above). They are characterized by particular patterns of outer membrane proteins and alleles of genes encoding house-keeping enzymes, rRNA gene restriction pattern, resistance to serum bactericidal activity, a 24-MDa plasmid (not present in all isolates), a unique antigenic variant of IgA1 protease, and the lack of D-xylose fermentation (Brenner et al., 1988a; Irino et al., 1988; Porto et al., 1989; Musser and Selander, 1990; Lomholt and Kilian, 1995). The taxonomic questions associated with *H. aegyptius* and its close relative *H. influenzae* are discussed above.

The mol% G + C of the DNA is: 39 (T_m).

Type strain: 180a of Pittman, ATCC 11116.

GenBank accession number (16S rRNA): M75044.

3. **Haemophilus aphrophilus** Khairat 1940, 505[AL]
a.phro′ phi.lus. Gr. n. *aphros* foam; Gr. adj. *philos* loving; M.L. adj. *aphrophilus* foam loving.

Short regular rods 0.45–0.55 × 1.5–1.7 µm with only occasional filamentous forms. Colonies on chocolate agar incubated in air supplemented with 10% extra CO_2 are high convex, granular, yellowish, and opaque and reach a diameter of 1.0–1.5 mm within 24 h. When plates are incubated without extra CO_2, the growth is characteristically stunted, with very small colonies interspersed with a few larger colonies. Grows on blood agar incubated in air plus CO_2 without feeder strain. Growth in broth media is granular, with a heavy sediment on the bottom of the tube and adhering colonies on the walls, which are difficult to remove.

H. aphrophilus possesses all the enzymes of the hemin biosynthetic pathway characteristic for hemin-independent species (White and Granick, 1963). Accordingly, it gives a positive, though usually weak, reaction for both porphobilinogen and porphyrins in the porphyrin test. The reason for an apparent need for hemin-containing media at primary isolation remains to be elucidated.

H. aphrophilus is a frequent member of the microflora of human dental plaque, particularly between the teeth and in the gingival pockets (Kraut et al., 1972; Kilian and Schiøtt, 1975). Occasionally causes endocarditis and brain abscesses in humans. Has been isolated from spinal fluid, wounds, and jaw infections (King and Tatum, 1962).

The mol% G + C of the DNA is: 42 (T_m).

Type strain: PM1, ATCC 33389, NCTC 5906.

GenBank accession number (16S rRNA): M75041.

4. **Haemophilus ducreyi** (Neveu-Lemaire 1921) Bergey, Harrison, Breed, Hammer and Huntoon 1923, 271[AL] (*Coccobacillus ducreyi* Neveu-Lemaire 1921, 20.)
du.crey′ i. M.L. gen. n. *ducreyi* of Ducrey; named after Ducrey, the bacteriologist who first isolated this organism.

Slender rods in pairs or chains, measuring 0.5 × 1.5–2.0 μm, often seen in "school of fish"-like arrangements. Capsules have not been detected. Growth is poor on most laboratory media. Colonies on chocolate agar after 72 h are predominantly small (~0.5 mm in diameter), flat, smooth, grayish, and translucent, but often with a few interspersed larger colonies having an otherwise identical appearance. Colonies may be slid intact across the surface of agar plates. Growth on blood agar is very sparse, and there is no satellite growth around *Staphylococcus* colonies. Produces a cell-associated hemolysin with cytotoxic activity (Alfa et al., 1996) and a soluble cytotoxin (Cope et al., 1997). Either one or both of these toxins results in weak β hemolysis on blood agar plates.

Clinical isolates usually appear to be asaccharolytic. However, under favorable growth conditions, some strains show a late positive reaction for glucose fermentation. The species is inert in most of the traditional biochemical tests (Tables BXII.γ.294 and BXII.γ.295), but produces a wide array of peptidases. At least seven variants have been detected among 105 clinical isolates based on cell protein profiles (Odumeru et al., 1983). Causes the human venereal disease known as soft chancre or chancroid. A carrier state in healthy individuals has not been detected.

The mol% G + C of the DNA is: 38 (T_m).
Type strain: CIP 542, DSM 8925.
GenBank accession number (16S rRNA): M63900, M75078.

5. **Haemophilus felis** Inzana, Johnson, Shell, Møller and Kilian 1999, 341[VP] (Effective publication: Inzana, Johnson, Shell, Møller and Kilian 1992, 2111.)
fe′ lis. L. n. *felis* a cat; L. gen. n. *felis* of a cat.

Coccobacilli or small regular rods, 0.45–0.55 × 1.5–1.7 μm, with occasional filamentous forms. Colonies on chocolate agar incubated in air plus 10% extra CO_2 are raised, smooth, and rounded and reach a diameter of 0.5–1.0 mm after 24 h. Colonies on brain–heart infusion agar supplemented with NAD are very adherent and show yellow pigmentation when collected on a loop. On blood agar, satellitic growth is observed around a feeder strain of *Staphylococcus* or an NAD-impregnated paper disk. Weak hemolysis is observed after incubation for 3 d. Requires increased concentration of CO_2 in incubation atmosphere for primary isolation. This requirement is lost upon subcultivation. Has been isolated from the lower respiratory tract of a cat with chronic obstructive pulmonary disease and from the nasopharynxes of 6 of 28 apparently normal cats.

The mol% G + C of the DNA is: 38 (T_m).
Type strain: TI189, ATCC 49733.
GenBank accession number (16S rRNA): AF224292.

6. **Haemophilus haemoglobinophilus** (Lehmann and Neumann 1907) Murray 1939, 309[AL] (*Bacterium haemoglobinophilus* (Lehmann and Neumann 1907, 270.)
hae.mo.glo.bi.no′ phi.lus. M.L. n. *haemoglobinum* hemoglobin; Gr. adj. *philos* loving; M.L. adj. *haemoglobinophilus* hemoglobin-loving.

Small, slightly pleomorphic, noncapsulated rods. Colonies on chocolate agar are smooth, convex, and translucent with a small granular area on top, and reach a diameter of 1–2 mm within 24 h. In contrast to other members of the genus, they grow well on blood agar and show no satellite growth around a streak of *Staphylococcus*.

Differs from all other *Haemophilus* species in lacking alkaline phosphatase. Belongs to the normal flora of the preputial sac of dogs, and is probably of low pathogenicity.

The mol% G + C of the DNA is: 38 (T_m).
Type strain: XIII of Kristensen, NCTC 1659.
GenBank accession number (16S rRNA): M75064.

7. **Haemophilus haemolyticus** Bergey, Harrison, Breed, Hammer and Huntoon 1923, 269[AL]
hae.mo.ly′ ti.cus. Gr. n. *haema* blood; Gr. adj. *lyticus* loosening, dissolving; M.L. adj. *haemolyticus* blood dissolving.

Small, regular, noncapsulated coccobacilli or short rods, with occasional filamentous forms. Colonies on chocolate agar are smooth, convex, grayish, and translucent and reach a diameter of 0.5–1.5 mm within 24 h. Produce clear hemolytic zones on bovine or sheep blood agar. However, the hemolytic activity may be lost upon subcultivation. Is found in the nasopharynx of a minority of the healthy human population and often in the bacterial deposits on human teeth below the gingival margin (subgingival dental plaque). No pathogenic potential has ever been demonstrated.

The mol% G + C of the DNA is: 39 (T_m).
Type strain: AQ/3273 of McIves, NCTC 10659.
GenBank accession number (16S rRNA): M75045.

8. **Haemophilus paracuniculus** Targowski and Targowski 1984, 355[VP] (Effective publication: Targowski and Targowski 1979, 36.)
pa.ra.cu.ni′ cu.lus. Gr. prep. *para* alongside of, resembling; L. n. *cuniculus* rabbit, or possibly the specific epithet of "*Haemophilus cuniculus*", a species that has never been described; M.L. adj. *paracuniculus* like "*Haemophilus cuniculus*".

Small coccobacilli or pleomorphic rods with occasional filamentous forms. In broth media supplemented with V factor, the organism forms chains of rods. Colonies on chocolate agar are smooth, high convex, grayish, and opaque. Capsules have not been described. Does not grow in phenol red broth base supplemented with V factor. Has been isolated from the gastrointestinal tract of rabbits with mucoid enteritis. The pathogenic significance of the organism has not been established.

The mol% G + C of the DNA is: 40 (Bd).
Type strain: RF15888, ATCC 29986.
GenBank accession number (16S rRNA): M75061.

9. **Haemophilus paragallinarum** Biberstein and White 1969, 77[AL]
pa.ra.gal.li.na′ rum. Gr. prep. *para* alongside of, resembling; M.L. gen. pl. n. *gallinarum* specific epithet; M.L. adj. *paragallinarum* resembling (*Haemophilus*) *gallinarum*.

Coccobacilli to pleomorphic rods with occasional filamentous forms. Most strains are capsulated. Colonies on chocolate agar are smooth, convex, grayish, and semiopaque and attain a diameter of 0.5–1.0 mm within 48 h in air supplemented with 10% CO_2. Growth is feeble in air without extra CO_2. Young cultures (8- to 24-h-old) of cap-

sulated strains produce iridescent colonies on transparent agar media. Growth is enhanced by serum added to cultivation media (Hinz, 1973; Rimler et al., 1976). Occasional V-factor-independent strains have been isolated in South Africa (Bisgaard Taxon 31) (Mouahid et al., 1992; Miflin et al., 1995).

Several serotyping schemes have been proposed. Three serovars (A–C) have been defined based on heat-labile surface antigens (Page, 1962). Kato and Tsubahara (1962) have used the designations I, II, and III for three serovars, of which serovar III may be a noncapsulated variant of serovar I (Kume et al., 1980). Hinz (1980) has established six serovars based on heat-stable somatic antigens. Nine serovars based on a hemagglutinin are currently recognized according to the proposal by Blackall et al. (1990a), which combines some of the former schemes in one, with the designations A-1, A-2, A-3, A-4, B-1, C-1, C-2, C-3, and C-4.

Produces neuraminidase and *N*-acetylneuraminate pyruvate lyase (Hinz and Müller, 1977). Present in the respiratory tract of poultry. Causes respiratory tract disease in chickens known as infectious coryza. The species includes organisms previously labeled *"Haemophilus gallinarum"*.

The mol% G + C of the DNA is: 42 (T_m).
Type strain: IPDH 2403, serovar A, ATCC 29545.
GenBank accession number (16S rRNA): M75057.

10. **Haemophilus parahaemolyticus** Pittman 1953, 750[AL]
pa.ra.hae.mo.ly' ti.cus. Gr. prep. *para* alongside of, resembling; M.L. n. *haemolyticus* specific epithet; M.L. adj. *parahaemolyticus* resembling (*Haemophilus*) *haemolyticus*.

Small, pleomorphic rods, usually with long, filamentous forms. Growth on chocolate agar is similar to that of *H. parainfluenzae*. A distinct β-hemolytic zone is produced on blood agar plates, most clearly detectable on bovine or sheep blood agar. Growth on blood agar usually is not restricted to the area around a feeder strain, presumably due to the release of ample V factor from blood cells that lyse as a result of the hemolytic activity.

Has been associated with acute pharyngitis, purulent oral infections, occasional cases of endocarditis, and exacerbation of chronic lower respiratory tract infections. Strains of this species produce an extracellular IgA1 protease closely related to the *H. influenzae* endopeptidase, which is capable of cleaving human IgAl (Kilian and Poulsen, unpublished studies). Tuyau and Sims (1974) observed neuraminidase activity in members of this species. However, this cannot be confirmed with well-defined chromogenic substrates (Kilian and Poulsen, unpublished studies). Hemolytic porcine isolates that were previously assigned to this species belong in the species *Actinobacillus pleuropneumoniae*.

The mol% G + C of the DNA is: 40–41 (T_m).
Type strain: 536, NCTC 8479.
GenBank accession number (16S rRNA): AJ295746.

11. **Haemophilus parainfluenzae** Rivers 1922, 431[AL]
pa.ra.in.flu.en' zae. Gr. prep. *para* alongside of, resembling; M.L. n. *influenzae* specific epithet; M.L. gen. n. *parainfluenzae* intended to mean like the species *H. influenzae*.

Small, pleomorphic rods, usually with long, filamentous forms. Occasional strains possessing a capsule have been described (Sims, 1970). Colonies on chocolate agar are grayish white or yellowish opaque and reach a diameter of 1–2 mm after 24 h. Some strains produce flat, smooth colonies with an entire edge, others show a serrated edge, and yet others grow as very rough wrinkled colonies. The irregular forms of colonies are usually coherent in texture and can be slid intact across the surface of the agar plate. Strains growing as rough-type colonies often convert into the smooth type after some *in vitro* transfers. Some isolates show week β-hemolysis on blood agar, but the property is often lost after several subcultivations. Growth in broth media may or may not be granulated.

Eight biovars have been identified based on three biochemical reactions: indole formation, and urease and ornithine decarboxylase activities (Table BXII.γ.294) (Kilian, 1976; Oberhofer and Bach, 1979; Bruun et al., 1984a; Doern and Chapin, 1987). It is not clear if strains with the characteristics of biovar V do indeed belong in the species *H. parainfluenzae*. They are phenotypically similar to *H. segnis* and *H. paraphrophilus*. The majority of human isolates can be assigned to biovars I–III.

H. parainfluenzae is ubiquitous in the human oral cavity and pharynx and may be present in the normal vaginal flora (Sims, 1970; Tuyau and Sims, 1975; Kilian and Schiøtt, 1975; Liljemark et al., 1984). Organisms closely resembling *H. parainfluenzae* have been isolated from monkeys, swine, rabbits, and rats (Kilian and Frederiksen, 1981a). Tuyau and Sims (1974) reported that the species has neuraminidase activity. However, this cannot be confirmed with well-defined chromogenic substrates. Is of low pathogenicity, but is occasionally implicated in endocarditis and lower respiratory tract infections in humans.

The mol% G + C of the DNA is: 40–41 (T_m).
Type strain: ATCC 33392, NCTC 7857 (biovar I).
GenBank accession number (16S rRNA): M75081.
Additional Remarks: Reference strains include NCTC 10665 (biovar II), NCTC 11607 (biovar III).

12. **Haemophilus paraphrohaemolyticus** Zinnemann, Rogers, Frazer and Deveraj 1971, 143[AL]
par.aph.ro.hae.mo.ly' ti.cus. M.L adj. *paraphro* resembling (*Haemophilus*) *aphrophilus*; M.L. adj. *haemolyticus* blood dissolving; M.L. adj. *paraphrohaemolyticus* like *H. aphrophilus*, but hemolytic.

When grown in air with 10% extra CO_2, it forms short to medium-length rods, 0.75–2.5 × 0.4–0.5 μm, with occasional short filaments; in air without added CO_2, it forms short to long, coarse rods with involution forms and twisted filaments. Requires increased CO_2 tension in incubation atmosphere for satisfactory growth and good β-hemolysis on blood agar. Apart from the CO_2 requirement, the biochemical, physiological, and ecological characteristics are similar to those of β-hemolytic isolates of *H. parainfluenzae*. Has been isolated from human sore throats, ulcers of the mouth, sputum, and urethral discharge of adult males, but pathogenic significance is unknown.

The mol% G + C of the DNA is: 40–41 (T_m).
Type strain: L1, NCTC 10670.
GenBank accession number (16S rRNA): M75076.

13. **Haemophilus paraphrophilus** Zinnemann, Rogers, Frazer and Boyce 1968, 418[AL]
pa.ra.phro' phi.lus. Gr. prep. *para* alongside of, resembling; M.L. adj. *aphrophilus* specific epithet; M.L. adj. *paraphrophilus* resembling (*Haemophilus*) *aphrophilus*.

Short, regular rods with occasional filamentous forms. Involution forms occur under fully aerobic incubation. Growth characteristics are identical to those described for *H. aphrophilus*. In contrast to *H. aphrophilus*, *H. paraphrophilus* requires V factor and is not dependent on X factor on primary isolation. The two species have otherwise almost identical properties (Tables BXII.γ.294 and BXII.γ.295) and are genetically closely related (see discussion under Taxonomic comments).

Found as a member of the normal flora of the human oral cavity and pharynx (Kilian and Frederiksen, 1981a). May cause subacute endocarditis, paronychia, and brain abscesses and has been isolated from osteomyelitis of the jaw, an inflamed appendix, urine of children with congenital malformation of urogenital tract, and the vaginas of mature women.

The mol% G + C of the DNA is: 42 (T_m).
Type strain: Reece, ATCC 29241, NCTC 10557.
GenBank accession number (16S rRNA): M75042.

14. **Haemophilus parasuis** Biberstein and White 1969, 77[AL]
pa.ra.su′ is. Gr. prep. *para* alongside of, resembling; M.L. n. *suis* specific epithet; M.L. adj. *parasuis* (*Haemophilus*) *suis*-like.

Thin, pleomorphic rods of varying length. Growth on chocolate agar is very feeble after 48–72 h. The colonies are smooth, grayish, and translucent and reach a diameter of about 0.5 mm. A marked enhancement of growth on chocolate agar, with colonies attaining a diameter of 1–2 mm, is seen around a streak of a *Staphylococcus* (Biberstein et al., 1977).

Some isolates form capsules, but capsule production does not appear to be associated with virulence. Some, but not all, capsules precipitate with Cetavlon and appear to be acidic polysaccharides (Morozumi and Nicolet, 1986). Four serovars (A–D) are designated, based on capsular polysaccharides (Bakos et al., 1952). Noncapsulated strains are antigenically heterogeneous. Based on heat-stable antigen extracts, a total of 15 serovars (1–15) have been described, and subsequent studies have suggested additional antigenic diversity (Kielstein and Rapp-Gabrielson, 1992; Blackall et al., 1997). Two variants (PAGE patterns I and II) have been identified based on differences in patterns of cellular proteins observed by polyacrylamide gel electrophoresis (Nicolet and Krawinkler, 1981; Morozumi and Nicolet, 1986).

Member of the normal flora of the upper respiratory tract of swine. Causes respiratory tract infections and polyserositis (Glässer's disease). Strains in culture collections labeled *"Haemophilus suis"* require only V factor and belong to *H. parasuis* according to the proposal of Biberstein and White (1969).

The mol% G + C of the DNA is: 41–42 (T_m).
Type strain: 1374 of Shope, NCTC 4557.
GenBank accession number (16S rRNA): M75065.

15. **Haemophilus segnis** Kilian 1976, 35[AL]
seg′ nis. L. adj. *segnis* slow, sluggish.

Pleomorphic rods, often showing a predominance of irregular, filamentous forms. Colonies on chocolate agar are smooth or granular, convex, grayish white, and opaque and reach a diameter of about 0.5 mm after incubation for 48 h. Growth in fermentation media is slow, and reactions are negative or weakly positive. Fermentation of sucrose is usually stronger than fermentation of glucose. Is a regular member of the human oral flora, particularly in dental plaque, and can be isolated from the pharynx. Has been isolated in pure culture from a pancreatic abscess.

The mol% G + C of the DNA is: 43–44 (T_m).
Type strain: HK 316, ATCC 33393, NCTC 10977.
GenBank accession number (16S rRNA): M75043.

Other Organisms

1. *"Haemophilus somnus"** Bailie 1966, 64 (*Haemophilus*-like organism, Kennedy, Biberstein, Howarth, Frazier and Dungworth 1960, 403; *Actinobacillus actinoides*-like organism, Bailie, Anthony and Weide 1966, 165; *Actinobacillus* sp., Gossling 1966, 18; *Haemophilus somnifer* Miles, Anthony and Dennis 1972, 431.)
som′ nus. L. masc. *somnus* sleep.

Gram-negative short rods, coccobacilli, or filaments. Most strains noncapsulated. Nonmotile. Not acid-fast. Colonial characteristics: 0.2–0.6 mm in diameter, raised, circular, smooth, entire colonies on beef blood agar after 24 h (Kennedy et al., 1960); 0.5–1.5 mm on PPLO–*Haemophilus* agar (Nicolet, 1971; Corboz and Nicolet, 1975); 1–2 mm after 3 d on brain–heart infusion calf blood–yeast extract plates (Garcia-Delgado et al., 1976). Prolonged incubation on blood agar produces colonies with a slightly granular appearance, papillate centers, and flattened peripheries. Most authors report no or weak hemolytic activity.

There is usually no growth of fresh isolates on infusion, tryptose, trypticase soy, serum, or hemoglobin agar under any atmospheric condition. Growth occurs on blood and chocolate agars, and on serum–yeast extract PPLO–agar under 5–20% carbon dioxide. Poor or no growth in ambient air, or anaerobically on any solid medium (Kennedy et al., 1960; Garcia-Delgado et al., 1976). Satellitic growth around *S. aureus* occurs in an atmosphere of increased CO_2, but the growth factor supplied by *S. aureus* has not been identified (Kennedy et al., 1960). Occasional strains lack the special atmospheric and nutritional requirements described, and all cultures apparently adapt gradually to fully aerobic growth. No growth response to X and V factors. Biochemical activities are shown in Tables BXII.γ.294 and BXII.γ.295.

All isolates examined have antigens in common, regardless of geographic and anatomic origin (Shigidi and Hoerlein, 1970; Corboz and Nicolet, 1975; Garcia-Delgado et al., 1976; Corboz and Wild, 1981). Cross-reactions at low titer with a number of other mostly Gram-negative bacteria have been reported (Miller et al., 1975). Significant diversity has been detected among isolates based on biochemical activities, plasmid profiles, and DNA fingerprinting (Fussing and Wegener, 1993).

Antimicrobial susceptibility: Only rough, qualitative data exist on antimicrobial susceptibility; these are based on nonstandardized disk diffusion tests. These suggest susceptibility to ampicillin, bacitracin, cephaloridine, chlorampheni-

**Editorial Note: "Haemophilus somnus"* has been described as a member of the genus *Haemophilus*. By current standards it does not qualify for inclusion in the genus.

col, dihydrostreptomycin, erythromycin, novobiocin, penicillin G, polymyxin B, and tetracycline, and resistance to lincomycin, neomycin, and sulfonamides (Garcia-Delgado et al., 1976).

Pathogenicity: *"H. somnus"* causes septicemia and meningoencephalomyelitis in cattle (Kennedy et al., 1960) and is involved in respiratory (Brown et al., 1970) and genital infections (Waldhalm et al., 1974a), including abortions (Chladeck, 1975), in that species. Experimental infections of mice, guinea pigs, rabbits, and sheep have been reported (Kennedy et al., 1960; Panciera et al., 1968; Miles et al., 1972).

Ecology: The reservoir of *"H. somnus"* appears to be the mucous membranes of the normal bovine respiratory and genital tracts (Corstvet et al., 1973; Waldhalm et al., 1974a).

The mol% G + C of the DNA is: 37.3 ± 0.2 (T_m).

GenBank accession number (16S rRNA): M75046.

2. *"Haemophilus agni"** Kennedy, Frazier, Theilen and Biberstein 1958, 645.

ag′ni. L. gen. n. *agri* of the lamb.

Morphology: Gram-negative, nonmotile, non-acid-fast, pleomorphic rods or coccobacilli, 0.3–0.7 × 0.5–2.0 µm. Long, thread-like forms containing spherical and thickened fusiform bodies occur. Pleomorphism diminishes on passage. Presence of capsules has been suggested.

Colonial characteristics: Colonial characteristics in 5–10% CO_2: the colonies are convex and translucent and range from <0.5–1.5 mm. Colonies become flattened peripherally and acquire more sharply contoured edges but not significantly larger size on further incubation.

Nutrition and growth conditions: Very slight growth on blood agar in air. Colonial growth on blood agar under 5–10% CO_2, as described above. Satisfactory growth occurs on hemoglobin cystine agar and chocolate agar. No growth response to X and V factors. No satellitic growth with staphylococci. No growth on MacConkey, tryptose, 10% equine serum (with and without 1% yeast hydrolysate), mycoplasma agar, coagulated blood serum, or gelatin.

Metabolism: Metabolism and biochemical activities are shown in Tables BXII.γ.294 and BXII.γ.295.

Antigenic structure: This organism cross-reacts consistently with *"H. somnus"*.

Antimicrobial susceptibility: Antimicrobial susceptibility has not been reported.

Pathogenicity: This organism is associated with septicemia, meningitis, polyarthritis myositis, pneumonia, and mastitis of sheep. Of experimental animals, only suckling mice are susceptible.

Ecology: The reservoir of *"H. agni"* has not been determined.

An organism occupying a position close to both *"H. agni"* and *"H. somnus"* has been encountered in a number of inflammatory diseases of sheep in Australia (Roberts 1956; Claxton and Everett 1966; Rahaley and White 1977) and New Zealand (Kater et al., 1962) and named *"Histophilus ovis"* (Roberts, 1956). De Ley et al., (1990) consider *"Histophilus ovis"* to be a senior synonym of *"H. agni"*.

The mol% G + C of the DNA is: 36.8 ± 0.3 (T_m).

Genus IV. **Lonepinella** *Osawa, Rainey, Fujisawa, Lang, Busse, Walsh and Stackebrandt 1996, 362^{VP} (Effective publication: Osawa, Rainey, Fujisawa, Lang, Busse, Walsh and Stackebrandt 1995b, 372)*

Ro Osawa and Erko S. Stackebrandt

Lone.pin.el′ la. M.L. fem. n. *Lonepinella* named after Lone Pine Koala Sanctuary, a private zoo in Australia.

Cells coccoidal, or short to extremely filamentous and rod-shaped. Facultatively anaerobic. Nonmotile. **Neither X nor V factor is required for growth.** No growth under 15°C or over 40°C; optimum, 37°C. Indole produced. Urea not hydrolyzed. **Produces gallic acid from tannic acid (tannase positive), and decarboxylates gallic acid to pyrogallol. Oxidase and catalase reactions are negative.** Acid, but not gas, is produced from D-glucose and some other carbohydrates. **Occur in the normal intestinal flora of the koala.** Analysis of 16 S rDNA places the genus into the family *Pasteurellaceae*, in the *Gammaproteobacteria*.

The mol% G + C of the DNA is: 37.5.

Type species: **Lonepinella koalarum** Osawa, Rainey, Fujisawa, Lang, Busse, Walsh and Stackebrandt 1996, 362 (Effective publication: Osawa, Rainey, Fujisawa, Lang, Busse, Walsh and Stackebrandt 1995b, 372.)

Further descriptive information

Based upon 16S rDNA analysis, isolates from the arboreal marsupial *Phascolarctos* (koala) form a separate branch within the radiation of members of the genera *Pasteurella*, *Haemophilus*, and *Actinobacillus*. Cells of *Lonepinella* strains are pleomorphic, including coccoidal forms (0.5–0.6 × 1.0–1.2 µm), short rods (0.5 × 3-5 µm), and extremely filamentous rods (0.5 × 50-100 µm), especially after prolonged incubation on plate media (Fig. BXII.γ.220). The organisms are nonmotile.

Polyamine composition of *Lonepinella* strains is characterized by the co-occurrence of putrescine and small amounts of diaminopropane, while cadaverine, tyramine, *sym*-norspermidine, spermidine, and spermine are lacking (Osawa et al., 1995b). This is in contrast to the other members of the family *Pasteurellaceae*, which have different polyamines (Busse et al., 1997). In addition, *Lonepinella* strains contain an unique, unidentified substance not reported in any other bacteria.

Lonepinella strains grow in nutrient broth supplemented with 0.1% yeast extract with uniform turbidity. On horse-blood supplemented Wilkins–Chalgren anaerobe agar or brain–heart infusion agar, smooth, opaque, more or less convex, gray to white colonies 1.0–3.0 mm in diameter without hemolysis are formed after 3 d at 37°C. No pigment is produced. Although *Lonepinella* strains are facultatively anaerobic, anaerobic conditions retard or suppress growth. Colony formation is also markedly suppressed on MacConkey agar. Optimum growth occurs at 37°C

**Editorial Note: "Haemophilus agni"* has been described as a member of the genus *Haemophilus*. By current standards it does not qualify for inclusion in the genus.

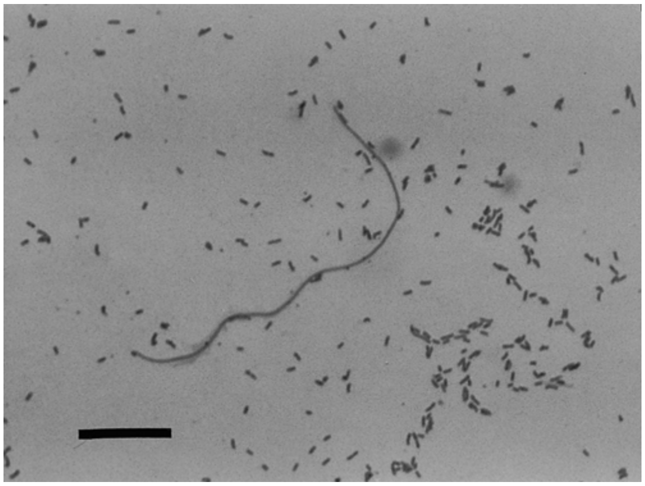

FIGURE BXII.γ.220. Gram-stained cells of *Lonepinella koalarum*, including an extremely long cell, from a colony formed on Wilkins–Chalgren anaerobe agar supplemented with 5% defibrinated horse blood after incubation at 37°C for 48 h. Bar = 20 μm.

when cultured in brain heart infusion. No growth occurs at 15°C or 40°C. Neither X nor V factor is required for growth.

After 3–4 d microaerophilic incubation at 37°C, *Lonepinella* strains form clear zones around colonies on a nonselective plate medium, the surface of which is treated with filter-sterilized tannic acid solution (Fig. BXII.γ.221). This indicates the ability to digest the tannin–protein complex formed on surface of the medium (Osawa, 1992).

Glucose, melibiose, rhamnose, sucrose, amygdalin, and L-arabinose are fermented without gas. D-mannitol, *myo*-inositol, and glucitol are not utilized. The Voges–Proskauer test and the β-galactosidase reaction are positive. The following enzyme activities are negative: oxidase, catalase, urease, arginine dihydrolase, lysine decarboxylase, ornithine decarboxylase, tryptophan deaminase, and gelatinase. H_2S and indole not produced.

Lonepinella is unique by virtue of its "tannase" (tannin acylhydrolase) activity, which hydrolyzes gallotannin to yield gallic acid. It was long believed that tannase could be produced only by fungal strains belonging to the genera *Aspergillus* (Pourrat et al., 1987) and *Candida* (Aoki et al., 1976), but recent studies have revealed an almost identical enzymatic activity in a bacterial species, *Streptococcus bovis* biotype I (currently proposed as a new species, "*S. gallolyticus*"; Osawa et al., 1995a]) (Osawa, 1990; Osawa et al., 1993c). *L. koalarum* is considered to be yet another bacterial species with tannase activity. This activity enables the organism to degrade the tannin–protein complex. Furthermore, the organism decarboxylates the released gallic acid to pyrogallol (Osawa et al., 1993c).

16S rDNA analysis revealed that *Lonepinella* does not belong to the family *Enterobacteriaceae*, but instead forms a phylogenetic cluster within the family *Pasteurellaceae*. Similarity values for strains of *Lonepinella* and members of the genera *Pasteurella*, *Haemophilus*, and *Actinobacillus* range from 93 to 94.5%. A similar range is found for the intra- and intergeneric relationships of the three genera. EMBL accession numbers are Y17189 (ACM 3666^T), Y17190 (strain ACM 3896), and Y17191 (strain ACM 3496). The mol% G + C content of the DNA, as determined by the thermal melting point method (Marmur and Doty, 1962), is 37.5.

Antibiotic sensitivity testing of two *L. koalarum* strains has indicated their resistance to vancomycin, but sensitivity to the following antimicrobials: kanamycin, colistin, chloramphenicol, erythromycin, oxytetracycline, penicillin, gentamicin, rifampin, and ampicillin (Osawa et al., 1995b).

Research on the ecology of *L. koalarum* has been stimulated by frequent isolation of the organism from fecal microflora of koala, an arboreal marsupial animal feeding exclusively on eucalyptus leaves (Osawa, 1992). The organism makes up more than 60% of the facultative anaerobic fecal microflora, and colonizes

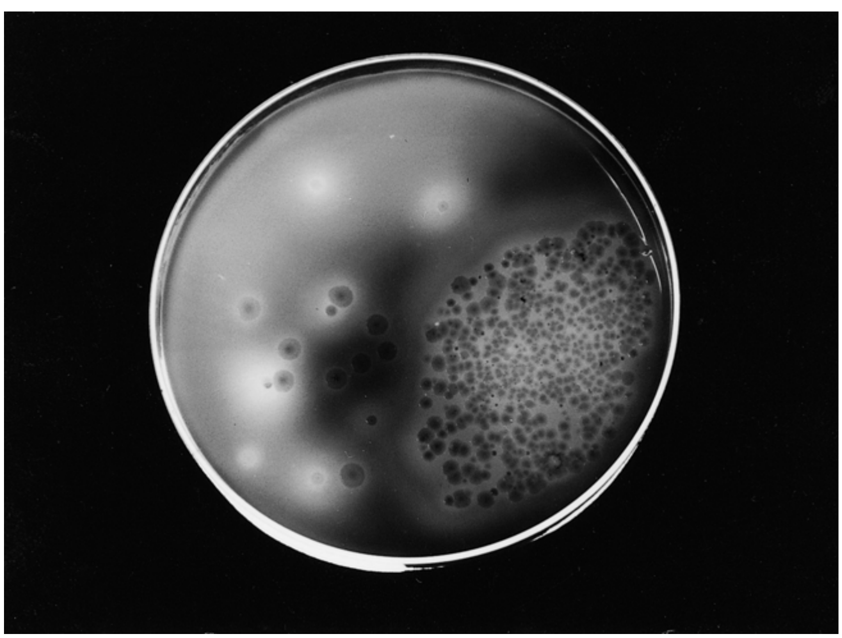

FIGURE BXII.γ.221. Growth of *Lonepinella koalarum*, with clear zones formed around colonies on vancomycin- and tannin-treated Wilkins–Chalgren anaerobe agar.

on the wall of the animal's well-developed caecum and proximal colon (Osawa et al., 1993a). Furthermore, a quantitative study on the microflora in "pap," a special maternal feces consumed by the juvenile around the time of dietary transition from maternal milk to eucalyptus leaves, revealed that "pap" has markedly higher viable counts of *L. koalarum* than the normal feces (Osawa et al., 1993b). The evidence strongly suggests that the organism plays a significant role in the digestion of a tannin-rich diet in the alimentary tract of the host animal.

Enrichment and Isolation Procedures

The best way of isolating *Lonepinella* from fecal samples is to inoculate a plate containing a selective agar, vancomycin- and tannin-treated Wilkins–Chalgren anaerobe agar (Osawa, 1992), and incubate it microaerophilically (5–15% O_2) at 37°C for 3 d. After incubation, *L. koalarum* colonies are easily distinguished from others in mixed cultures, because they are generally about 1–2 mm in diameter with distinct clear zones around them (due to degradation of the tannin–protein complex formed on the surface of the plate). However, the plate allows growth of some enterobacterial species, including *Escherichia coli* and *Klebsiella*; thus, detection of the target colony might be difficult in fecal samples containing a large number of enterobacteria. The organism is readily cultured in conventional enrichment liquid media, such as nutrient broth and heart infusion broth, incubated at 37°C.

Maintenance Procedures

Plate and broth cultures of *Lonepinella* species usually survive no longer than 1 week without subcultivation. Survival is better at room temperature than at 4°C. The most satisfactory way of conserving cultures is by lyophilization, e.g., in skim milk. Wilkins–Chalgren anaerobe agar cultures remain viable for at least 1 year when frozen at −70°C in sealed glass ampoules.

Procedures for Testing Special Characters

Test for tannase activity Tannase activity may be directly detected by the clear-zone formation of colonies grown on the selective tannin-treated plate medium (Osawa, 1992). The specific clear zone is, however, sometimes difficult to recognize due to overgrowth of other bacteria in the samples. For a more definite and reliable detection of tannase activity, a visual reading method developed by Osawa and Walsh (1993) should be performed. This method is based on two phenomena: (i) the ability of tannase to hydrolyze methyl gallate, which has a molecular structure similar to gallotannin, to release free gallic acid and (ii) the green coloration of gallic acid after prolonged exposure to oxygen under alkaline conditions. Briefly, the isolate is cultured on Wilkins-Chalgren anaerobe agar aerobically at 37°C for 3 d. After incubation, fresh culture on the plate is suspended in substrate medium containing NaH_3PO_4 (33 mM) and methyl gallate (20 mM) to prepare a dense suspension (equivalent to a no. 3 McFarland turbidity standard). The suspension is then incubated aerobically at 37°C for 24 h. After incubation, the suspension is alkalinized with an equal amount of saturated $NaHCO_3$ solution and left in the atmosphere at room temperature for at least 15 min. The development of any green coloration in the medium is an indication of tannase activity.

Test for gallate decarboxylase activity In addition to tannase activity, *Lonepinella* strains are capable of decarboxylating gallic acid to pyrogallol. The most rapid and convenient method to detect this activity was developed by Osawa and Walsh (1995). Briefly, the isolate is inoculated into Wilkins–Chalgren anaerobe broth or nutrient broth supplemented with gallic acid (10 mM), and incubated anaerobically at 37°C for 3 d. After incubation, the culture is centrifuged, and the supernatant added to an equal amount of saturated $NaHCO_3$ solution. Any orange coloration of the medium that develops is an indication of positive gallate decarboxylating activity.

Differentiation of the genus *Lonepinella* from other genera

See Table BXII.γ.297 for major phenotypic characteristics that differentiate *Lonepinella* from *Pasteurella*, *Haemophilus*, and *Actinobacillus*.

Taxonomic Comments

Lonepinella strains were initially placed within the family *Enterobacteriaceae*, since they are facultatively anaerobic, oxidase-negative, Gram-negative bacilli and reduce nitrates to nitrites, thus phenotypically resembling *Enterobacter agglomerans* (Osawa, 1992). However, further comparison with representatives of the *Gammaproteobacteria* has shown them to group within the radiation of organisms presently assigned to the family *Pasteurellaceae* (Osawa et al., 1995b). The phylogenetic placement of these *Phascolarctos* isolates within members of the family *Pasteurellaceae* was unexpected, as none of the species of the family known at the time, *Pasteurella*, *Haemophilus*, or *Actinobacillus*, had been reported to produce tannase and gallate decarboxylase (Mannheim, 1984). The rationale for describing the isolates as a species of a new genus, *Lonepinella*, was based on these physiological properties, their origin from feces of the koala, and the phylogenetic distinctness from the type species of the *Pasteurellaceae* genera. As demonstrated by the studies of Dewhirst et al. (1992, 1993), the phylogenetic structure of the family does not reflect the taxo-

TABLE BXII.γ.297. Differential phenotypic characteristics of the genus *Lonepinella* and other genera[a]

Characteristics	*Lonepinella*	*Actinobacillus*	*Haemophilus*	*Pasteurella*

[a]For symbols, see standard definitions.

nomic affiliation of species into genera to which they presently belong (Fig. BXII.γ.222). On the other hand, the branching points of deeply rooting lineages have no high statistical significance, as is demonstrated by low (<80%) bootstrap values (Fig. BXII.γ.222). Thus, the branching point of the species *Lonepinella koalarum* changes with the number and selection of reference species. However, the distinctness of the *Lonepinella* lineage has not been changed by either the composition of strains included in the phylogenetic trees or by the algorithm used for their generation.

List of species of the genus Lonepinella

1. **Lonepinella koalarum** Osawa, Rainey, Fujisawa, Lang, Busse, Walsh and Stackebrandt 1996, 362[VP] (Effective publication: Osawa, Rainey, Fujisawa, Lang, Busse, Walsh and Stackebrandt 1995b, 372.)
koala' rum. Eng. n. *koala* an arboreal marsupial, *Phascolarctus cinereus,* called "koala"; L. gen. pl. *koalarum* of koalas.

The description is as given for the genus. Cells coccoidal, 0.5–0.6 × 1.0–1.2 µm, or short to extremely filamentous and rod-shaped, 0.5–0.6 um × 3–100 µm. D-glucose, sucrose, and amygdalin are utilized at 37°C within 48 h, with the production of acid, but not gas. D-mannitol, *myo*-inositol, and glucitol not utilized. Tannase and gallate decarboxylase positive.

Occurs in the normal intestinal flora of koalas; probably providing the animals with digests of tannin-rich eucalyptus leaves in their hind-gut.

The mol% G + C of the DNA is: 37.5 (T_m).

Type strain: ACM 3666, ATCC 700131, DSMZ 10053.

GenBank accession number (16S rRNA): Y17189.

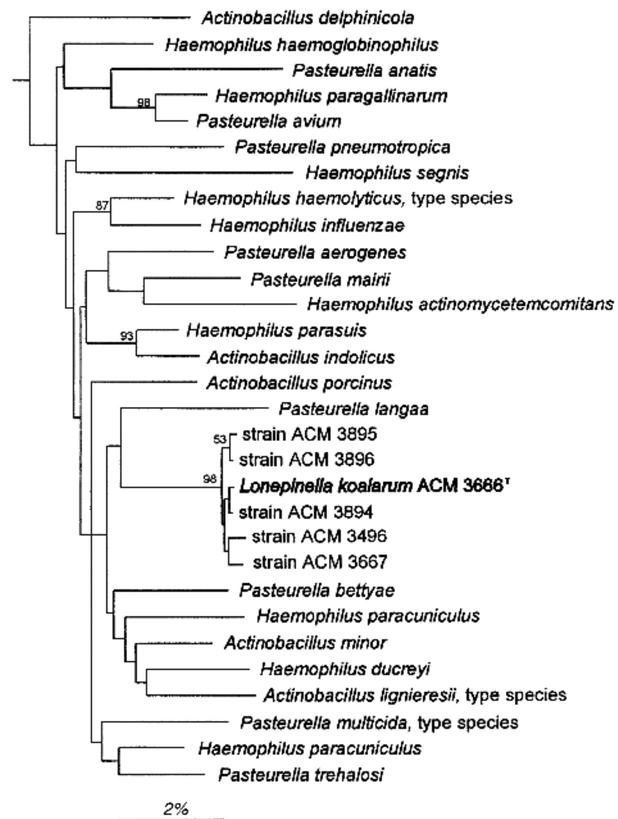

FIGURE BXII.γ.222. Dendrogram of 16S rDNA relationships of strains of the species *Lonepinella koalarum* and some selected members of the family *Pasteurellaceae* that represent individual lines of descent (Dewhirst et al., 1992, 1993; Osawa et al., 1995b). The type species of *Pasteurella*, *Haemophilus*, and *Actinobacillus* are indicated. The dendrogram was generated using the algorithm of Saitou and Nei (1987) on dissimilarity values, as calculated by Jukes and Cantor (1969). The sequences of some members of the *Enterobacteriaceae* were used as the root. Numbers refer to bootstrap values (300 trees). Only values higher than 80% are presented. Bar = 2% sequence divergence.

Genus V. **Mannheimia** *Angen, Mutters, Caugant, Olsen and Bisgaard 1999a, 82[VP]*

Reinier Mutters, Øystein Angen and Magne Bisgaard

Mann.hei' mi.a. L. n. fem. *Mannheimia* named in tribute to the German microbiologist Walter Mannheim.

Gram-negative, nonmotile rods or coccobacilli. Cell diameters of ~0.5 × 1.2 µm are similar to those of *Pasteurella* species. **Some species exhibit bipolar staining.** Endospores are not formed. Growth is mesophilic and facultatively anaerobic or microaerophilic. Neither X nor V factor is required for growth. Glucose is fermented without gas production. **Oxidase reaction is normally positive**, but may be variable. **Alkaline phosphatase test is positive** and **nitrate is reduced**. Simmon's citrate, arginine dihydrolase, and Voges–Proskauer tests are negative, and there is no fermentation of D-adonitol or L-sorbose. All strains ferment D-mannitol. Urease reaction is negative. Trehalose and D-mannose are not fermented. Cultural characteristics are typical of those of the

family *Pasteurellaceae*. A zone of **β-hemolysis is commonly observed**, depending on media, type of blood, and pH.

The mol% G + C of the DNA is: 39.2–43.9.

Type species: **Mannheimia haemolytica** (Newsom and Cross 1932) Angen, Mutters, Caugant, Olsen and Bisgaard 1999a, 82 (*Pasteurella haemolytica* Newsom and Cross 1932, 715.)

Further descriptive information

Maximum likelihood analysis of 16S rDNA sequences of *Mannheimia* strains results in five distinct but affiliated clusters (Angen et al., 1999a). The mean sequence differences within each cluster range from 0.9 to 2.5%, while the mean sequence differences between the five clusters range from 2.8 to 4.4%. Bootstrap analysis identifies clusters II–V as monophyletic in more than 80% of the repeats. Strains of cluster I, however, cluster together in only 39% of the repeats.

Cluster I includes the type strain of the genus, *M. haemolytica* (NCTC 9380, GenBank accession no. AF060699). Differences in only two nucleotide positions separate this strain from strain U57066 which has the same sequence as strains of serovars 1, 5–9, 12–14, 16, and UG1 of the former *P. haemolytica* (Davies et al., 1996). These two sequences cluster together in 71% of the bootstrap trees. Cluster I also includes *M. glucosida*, the sequences of which show considerable heterogeneity and do not appear as a monophyletic group in the phylogenetic analysis (Angen et al., 1999a). Clusters II–IV contain *M. ruminalis*, *M. granulomatis*, and *M. varigena*, respectively. Cluster V currently includes only unnamed taxa. The genus *Mannheimia* is most closely related to the genus *Actinobacillus,* as evaluated by distances to the type species of *Pasteurella*, *Actinobacillus*, and *Haemophilus*.

The polyamine patterns of the five named species of *Mannheimia* can be obtained from the publication of Busse et al. (1997). Members of the genus are characterized by the presence of 1,3-diaminopropane as the predominant compound (77.6–95.2%), followed by spermine (2.2–12.8%), spermidine (1.7–11.6%), putrescine (0.8–3.8%), and cadaverine (0.2–1.1%). The variations observed are on the same order as those observed for the type strains of the three subspecies of *P. multocida*.

Surface colonies on bovine blood agar are generally circular, slightly raised, and regular, with an entire margin. The surface of the colonies is regular, smooth, shiny, and non-transparent, with a grayish tinge. A diameter of ~1–2 mm is observed after 24 h aerobic incubation at 37°C. A narrow zone of β-hemolysis normally surrounds the colonies, which have a butyrous consistency, but weakly hemolytic strains are often isolated. The colony size of strains isolated from pigs is generally smaller. These strains, however, often produce a very distinct zone of β-hemolysis.

Organisms in Gram-stained preparations from the above cultures are rather pleomorphic without a distinctive cellular morphology. All strains grow well in commonly used broths and in conventional media used for phenotypic characterization. Growth occurs between 25°C and 40°C, with an optimum temperature of 37°C.

As with most *Pasteurella sensu stricto* and actinobacilli, the recovery of *Mannheimia* spp. from clinical specimens does not normally present a problem unless the material is contaminated. When plates are overgrown by *Proteus* spp., the specimen should be replated on blood agar containing an increased amount of agar or a detergent. Media such as trypticase soy blood agar base (BBL), Difco–tryptose blood agar base, or Oxoid–Columbia blood agar base containing 5% bovine or ovine blood are generally preferred for initial isolation. The degree of hemolysis is dependent on the medium used and on the animal species from which the blood originates. A selective medium for isolation of *M. haemolytica* from specimens containing mixed populations of bacteria has been described by Morris (1958).

DNA–DNA hybridization data are available for 102 pairs of strains (Angen et al., 1999a). DNA binding of 91% is observed between the type strain of *M. haemolytica* and the most divergent strain within the ribotype cluster containing the type strain. The different biovars of *M. glucosida* cluster above 85% DNA binding by single linkage. The group of the *M. glucosida* biovars clusters with the type strain of *M. haemolytica* at a DNA binding level of 71%. Strains classified as *M. ruminalis* cluster at 88% DNA binding, while strains identified as *M. granulomatis* cluster at a DNA binding level of 86%. A maximum level of 85% DNA binding is observed for strains identified as *M. varigena*.

Several candidates for new species of *Mannheimia* have been identified by Angen et al. (1999a). However, several taxa allocated to this genus remain to be characterized by DNA–DNA hybridization. Further DNA–DNA hybridizations are necessary before conclusions as to the taxonomic interrelationships between these taxa can be drawn.

Information as to the use of ribotyping, random amplified polymorphic DNA analysis, and pulsed-field gel electrophoresis for discrimination of the former *P. haemolytica* complex may be obtained from the publication of Kodjo et al. (1999). For review of the structure, function, and properties of cellular and extracellular components of *P. haemolytica* see Adlam (1989), while the molecular approach for isolating genes from *M. haemolytica* A1 that code for secreted and soluble antigens has been reviewed by Lo (1995). Major outer membrane proteins of *M. haemolytica* serovars 1–15 have been investigated by Morton et al. (1996).

Since previous publications based upon a few phenotypic tests and subsequent serotyping might be questioned, reinvestigations are needed to obtain solid data on the ecology, antibiotic sensitivity, and pathogenicity of species of the genus *Mannheimia*.

Maintenance Procedures

Proper maintenance of cultures of members of the genus *Mannheimia* includes subculturing on complex media. Cultures remain viable for no longer than a week under refrigeration. Plates should be kept in plastic bags to avoid drying. For long term preservation, lyophilization or storage at −80°C in nutrient broth containing glycerol or a mixture of glucose and serum is recommended.

List of species of the genus Mannheimia

1. **Mannheimia haemolytica** (Newsom and Cross 1932) Angen, Mutters, Caugant, Olsen and Bisgaard 1999a, 82[VP] (*Pasteurella haemolytica* Newsom and Cross 1932, 715.)
hae.mo.ly′ti.ca. Gr. n. *haima* blood; Gr. n. *lysis* solution; adj. from *lyticos,* Latinized as M.L. fem. adj. *lytica* dissolving, referring to the hemolysis seen on blood agar.

Corresponds to *P. haemolytica* biogroup 1 (Bisgaard and Mutters, 1986b). Cells are Gram-negative, nonmotile, small rods and coccobacilli. Colonies are regular, smooth, and grayish on blood agar and are 1–2 mm in diameter after 24 h of incubation. Most strains show a characteristic β-hemolysis on bovine blood agar. Biochemical characteristics

important for characterization are listed in Tables BXII.γ.298 and BXII.γ.299 and under the description of genus *Mannheimia*. D-sorbitol, D-xylose, maltose, and dextrin are fermented. No strains ferment L-arabinose or glucosides. Strains are negative in ornithine decarboxylase and NPG (β-glucosidase) and positive in ONPF (α-fucosidase). Isolated from pneumonia in cattle and sheep and from septicemia in lambs and mastitis in ewes. Some of the serotypes are probably part of the resident microflora of the upper respiratory tract of ruminants (Frank, 1989; Gilmour and Gilmour, 1989).

A total of 17 serovars have been described within *M. haemolytica*, among which serovars T3, 4, 10, and 15 now are classified as *"Pasteurella trehalosi"*. Representatives of serovars A1, 2, 5, 6, 7, 8, 9, 12, 13, 14, and 16 are found in *Mannheimia haemolytica*. Serotype 11 has been reclassified as *Mannheimia glucosida*.

Virulence factors and pathogenesis of *M. haemolytica* in cattle have been reviewed by Confer et al. (1995). Most studies on pathogenesis and virulence factors have been done with strains classified as serotype A1, which should represent *M. haemolytica* (Bisgaard and Mutters, 1986b; Davies et al., 1996; Angen et al., 1999a). Several potential virulence factors have been described, including the polysaccharide capsule (Chae et al., 1990), LPS (Brogden, 1992), neuraminidase (Straus et al., 1993), transferrin binding proteins (Ogunnariwo and Schryvers, 1990), and sialoglycoprotease (Abdullah et al., 1991). Production of a leucotoxin has been observed in all serotypes, as well as in several untypable strains (Chang et al., 1987; Burrows et al., 1993). It has been shown to be specific for bovine macrophages, neutrophils, lymphocytes, and platelets (Clinkenbeard and Upton, 1991), and several studies have indicated that it plays a major role in the pathogenesis of pneumonic pasteurellosis (Henricks et al., 1992; Hughes et al., 1994; Tatum et al., 1998).

The type strain was isolated in 1956 from sheep in the UK. The type strain represents serovar A2, is ONPX (β-xylosidase) and ONPG negative and shows a late *meso*-inositol fermentation.

The mol% G + C of the DNA is: 43.6 (T_m).

Type strain: J.A.Watt 1266A&B, CCUG 12392, NCTC 9380.

GenBank accession number (16S rRNA): AF060699.

2. **Mannheimia glucosida** Angen, Mutters, Caugant, Olsen and Bisgaard 1999a, 83[VP]

glu.co' si.da. Gr. adj. *glykos* sweet; L. adj.-forming suff. *-id (-us)*; fem. *-ida*; M.L. adj. *glucosida* pertaining to glucosides, which are fermented by almost all biovars.

Corresponds to Frederiksen's third taxon of *M. haemolytica* (Frederiksen, 1973), classified as *P. haemolytica* biogroups 3 and 5 by Bisgaard and Mutters (1986b) and reclassified as *M. haemolytica* biogroups 3A–H by Angen et al. (1997). The species also includes NPG and *meso*-inositol positive strains of *M. haemolytica* biogroup 9 (Bisgaard and Mutters, 1986b). *M. glucosida* can be divided into 9 biovars, A–I (Angen et al., 1999a). Cells are Gram-negative, nonmotile, small rods. Colonies are regular, smooth, and grayish on blood agar and are 1–2 mm in diameter after 24 h of incubation. All strains are hemolytic on bovine blood agar. All strains ferment D-sorbitol, D-xylose, maltose, and dextrin. For the ONPG and NPG tests, all biovars are positive. The biovars are separated by differences in ornithine decarboxylase, ONPX, ONPF, and fermentation of L-arabinose and glucosides. Further biochemical characteristics are listed in Tables BXII.γ.298 and BXII.γ.299 and under the description of genus *Mannheimia*. Typeable strains within *M. glucosida* all belong to serovar A11 (Angen et al., 1999b). Most strains investigated have been isolated from sheep, although isolates of serotype 11 have been reported from cattle (Quirie et al., 1986). This group of bacteria is normally not associated with disease and probably represents part of the resident microflora in the upper respiratory tract (Biberstein and Gillis, 1962). Murray et al. (1992) have shown that the iron binding proteins in serotype A11 differed from other serotypes. Sialoglycoprotease and neuraminidase activity have not been observed within serotype A11 (Lee et al., 1994). Serotype A11 produces a leucotoxin that is serologically and functionally similar to leucotoxin from *M. haemolytica* (A1), but immunoblots have shown that strains of serotype A11 seem to produce more variants of these toxins than do the other serotypes (Burrows et al., 1993).

The type strain was originally received as B558 from Moredun Research Institute. It was isolated from ovine lung in the UK, and belongs to biovar B and serotype 11 (Angen et al., 1997).

The mol% G + C of the DNA is: 41.6 (T_m).

GenBank accession number (16S rRNA): AF053889.

3. **Mannheimia granulomatis** (Ribeiro, Carter, Frederiksen and Riet-Correa 1990) Angen, Mutters, Caugant, Olsen and Bisgaard 1999a, 82[VP] (*Pasteurella granulomatis* Ribeiro, Carter, Frederiksen, and Riet-Correa 1990, 105.)
gran.nu.lo′ma.tis. L. dim. n. *granulum* a small grain; Gr. suff. *-oma* a swelling or tumor; M.L. n. *granuloma* a granuloma; M.L. n. *granulomatis* of a granuloma.

Cells are Gram negative, nonmotile, small rods and coccobacilli. Colonies are regular, smooth, and grayish on blood agar and are 1–2 mm in diameter after 24 h of incubation. No strains were hemolytic on bovine blood agar, but they have been reported as hemolytic using ovine blood (Ribeiro et al., 1989). All strains are negative for ornithine decarboxylase and ONPF and positive for NPG and fermentation of D-sorbitol. Strains are variable in fermentation of D-xylose, maltose, dextrin, glucosides, and *meso*-inositol.

[b]Incubation temperature 37°C.

[c]strains of Bisgaard Taxon 36 are positive.

Further biochemical characteristics are listed in Tables BXII.γ.298 and BXII.γ.299 and under the description of genus *Mannheimia*. The species includes the following taxa: *Pasteurella granulomatis*, isolated from bovine panniculitis (Ribeiro et al., 1989; 1990; Riet-Correa et al., 1992); Bisgaard Taxon 20 biovars 1 and 2, isolated from bronchopneumonia and conjunctivitis in leprine species and deer (Devriese et al., 1991); and *M. haemolytica* biogroup 3J, isolated from deer and the oral cavity of cattle (Angen et al., 1997). No virulence factors have yet been described.

The type strain was isolated from bovine panniculitis in Brazil and was previously classified as *Pasteurella granulomatis* (Ribeiro et al., 1989). The type strain is ONPG positive and ferments maltose, dextrin, glucosides, and *meso*-inositol, but not D-xylose.

The mol% G + C of the DNA is: 39.2 (T_m).

Type strain: 26, ATCC 49244.

GenBank accession number (16S rRNA): AF053902.

4. **Mannheimia ruminalis** Angen, Mutters, Caugant, Olsen and Bisgaard 1999a, 83.[VP]

ru.mi.na'lis. L. n. *rumen* stomach, especially first stomach of ruminants; L. adj.-forming suff. *-alis*; M.L. adj. *ruminalis* referring to ruminants, from which the bacteria have been isolated.

Cells are Gram-negative, nonmotile, nonhemolytic, small rods or coccobacilli. Colonies are regular, smooth, and grayish on blood agar and are 1–2 mm in diameter after 24 h of incubation. All strains are ornithine decarboxylase, NPG, ONPF, and ONPX negative and do not ferment L-arabinose, *meso*-inositol, or glucosides (Table BXII.γ.298). Further biochemical characteristics are given in the description of genus *Mannheimia*. *M. ruminalis* consists of two distinct phenotypic groups. Biovar 1 consists of strains that do not ferment maltose or dextrin, show variable reactions for fermentation of D-sorbitol and D-xylose, and correspond to Bisgaard Taxon 18 biovars 1 and 3 (Bisgaard et al., 1986). Biovar 2 strains ferment maltose and dextrin and correspond to *M. haemolytica* biogroup 8D (Angen et al., 1997). All strains have been isolated from the rumen of sheep or cattle and are not associated with disease. Virulence factors have not been described. The strains have previously been called *Actinobacillus lignieresii* (Phillips, 1961, 1964, 1966).

The type strain was originally isolated as strain S1/15/6 from a sheep rumen in the UK by J.E. Phillips, and previously was classified as Bisgaard Taxon 18 biovar 1 (Bisgaard et al., 1986). The type strain belongs to biovar 1 and does not ferment D-sorbitol and D-xylose.

The mol% G + C of the DNA is: not known.

Type strain: HPA 92,CCUG 38470.

Additional Remarks: AF053900.

5. **Mannheimia varigena** Angen, Mutters, Caugant, Olsen and Bisgaard 1999a, 83.[VP]

va.ri'gena. L. fem. adj. *varia* varied; L. adj.-forming element *-gena* originating from; L. adj. *varigena,* of different origin, referring to the fact that strains of this species have been isolated both from ruminants and pigs.

Cells are Gram-negative, nonmotile, small rods or coccobacilli. Colonies are regular, smooth, and grayish on blood agar and are 1–2 mm in diameter after 24 h of incubation. Most strains are hemolytic on bovine blood agar. All strains ferment L-arabinose and D-xylose, but not D-sorbitol. Most strains do not ferment glucosides; those fermenting glucosides also ferment D-melibiose. Most strains are ornithine decarboxylase positive (biovar 1) and correspond to *M. haemolytica* biogroup 6, Bisgaard Taxon 36, and Bisgaard Taxon 15 biovar 1. Ornithine-decarboxylase-negative strains (biovar 2) were isolated from pigs and correspond to Bisgaard Taxon 15 biovar 2. Strains of *M. varigena* have been isolated from pneumonia, mastitis, and septicemia in cattle, as well as from the oral cavity, rumen, and intestines (Angen et al., 1997). Isolates from pigs have been associated with septicemia, enteritis, and pneumonia and have also been isolated from the upper respiratory tract (Bisgaard, 1984; McLaughlin et al., 1991). Some of these strains have been shown to produce a leucotoxin toxic against leucocytes from both cattle and pigs (Chang et al., 1993).

The type strain was isolated from a bovine with pneumonia in West Germany, and was previously classified as *M. haemolytica* biogroup 6 (Bisgaard and Mutters, 1986b). This strain is indole negative, ONPG and ONPF positive, and NPG negative and ferments maltose and *meso*-inositol, but not dextrin (Tables BXII.γ.298 and BXII.γ.299).

The mol% G + C of the DNA is: 41.7 (T_m).

Type strain: 177, CCUG 38462.

GenBank accession number (16S rRNA): AF053893.

Genus VI. **Phocoenobacter** *Foster, Ross, Malnick, Willems, Hutson, Reid and Collins 2000, 138[VP]*

GEOFFREY FOSTER AND MATTHEW D. COLLINS

Pho.coe.no.bac' ter. M.L. n. *phocoena* derived from Gr. n. *phokaina* porpoise; M.L. masc. n. *bacter* rod; M.L. masc. n. *phocoenobacter* a rod from a porpoise.

Cells spherical, ovoid or rod shaped, 0.2–0.5 × 0.5–1.0 μm. Occasional longer forms occur. **Some cells demonstrate bipolar staining.** Gram negative. **Nonmotile. Facultative anaerobes.** Optimum temperature for growth, 37°C. Do not require X or V factors for growth. No growth occurs on MacConkey agar. **Catalase negative, oxidase positive. Nitrates are reduced to nitrites. Voges–Proskauer positive.** Arginine dihydrolase, ornithine decarboxylase, lysine decarboxylase, urease and indole are not produced. Acid produced from glucose. Isolated from a porpoise.

The mol% G + C of the DNA is: 41.5.

Type species: **Phocoenobacter uteri** Foster, Ross, Malnick, Willems, Hutson, Reid and Collins 2000, 139.

FURTHER DESCRIPTIVE INFORMATION

Cells are pleomorphic after isolation, with coccal, coccobacillary, and bacillary forms all present. After 48 h incubation on sheep blood agar, colonies are 0.5 mm in diameter, circular, entire, low convex, smooth, and gray. Colonies are not sticky on primary isolation. Nonhemolytic on sheep blood agar initially, although alpha hemolysis is evident in older cultures. Growth on Columbia agar without serum or blood is absent but a scanty growth may be obtained on tryptic soy agar without additives. Grows at 37°C and 22°C, but not at 42°C.

Because the genus contains only one species, all the characteristics given for the genus also describe the species *Phocoenobacter uteri.*

ENRICHMENT AND ISOLATION PROCEDURES

Phocoenobacter strains can be isolated on blood-containing media. Growth is poor or absent on media without blood. Increased CO_2 does not enhance the number or size of the colonies.

MAINTENANCE PROCEDURES

Surface cultures survive up to a week on Columbia sheep blood agar and slightly longer on blood-enriched nutrient agar slopes. Both lyophilization and storage on cryobeads at −80°C are effective for long-term maintenance.

DIFFERENTIATION OF THE GENUS *PHOCOENOBACTER* FROM OTHER GENERA

Phocoenobacter can be differentiated from all other members of the *Pasteurellaceae* by the following tests. It can be separated from *Pasteurella* by its negative catalase, indole, and D-mannose reactions; from *Haemophilus* by its positive Voges–Proskauer reaction and lack of X or V requirement; from *Actinobacillus* by not producing urease; from *Mannheimia* by its negative catalase and mannitol fermentation reactions; and from *Lonepinella* by its positive oxidase reaction.

TAXONOMIC COMMENTS

The genus *Phocoenobacter* was described to accommodate a Gram-negative pleomorphic rod originating from the uterus of a porpoise. The genus is phylogenetically related to the *Pasteurellaceae.*

The family *Pasteurellaceae* is phylogenetically very complex and there is extensive intermixing of species of some of its constituent genera. The genus *Phocoenobacter* forms a distinct subline within the *Pasteurellaceae* and does not display a particularly close affinity with any described species of the family. The nearest named relative of *Phocoenobacter* in terms of 16S rDNA sequence similarity is *Haemophilus ducreyi*, but treeing analysis shows this association is statistically not significant.

List of species of the genus Phocoenobacter

1. **Phocoenobacter uteri** Foster, Ross, Malnick, Willems, Hutson, Reid and Collins 2000, 139[VP]
   u' te.ri. L. masc. n. *uteris* uterus.

   The characteristics are as described for the genus and as listed in Table BXII.γ.300. Acid is produced from glucose but not from adonitol, dulcitol, galactose, inositol, inulin, lactose, maltose, mannitol, mannose, melibiose, raffinose, rhamnose, salicin, sorbitol, sucrose, trehalose, or xylose. β-galactosidase positive. Alkaline phosphatase, esterase lipase, acid phosphatase, and naphthol- AS-BI-phosphohydrolase are positive. Leucine arylamidase is weakly positive.

   The mol% G + C of the DNA is: 41.5 (T_m).
   Type strain: NCTC 12872, M1063U/93.
   GenBank accession number (16S rRNA): X89379.

TABLE BXII.γ.300. Characteristics of *Phocoenobacter uteri*[a]

Characteristics	Reaction or result
Production of:	
Catalase	−
Oxidase	+
Indole	−
Arginine dihydrolase	−
Lysine decarboxylase	−
Ornithine decarboxylase	−
Acetoin	+
β-Galactosidase (ONPG)	+
Fermentation of:	
Glucose	+
Adonitol, dulcitol, galactose, inositol, inulin, lactose, maltose, mannitol, mannose, melibiose, raffinose, rhamnose, salicin, sorbitol, sucrose, trehalose, xylose	−
Growth on MacConkey agar	−
X or V factor requirement	−

[a]Symbols: +, positive; −, negative.

Index of Scientific Names of *Archaea* and *Bacteria*

Key to the fonts and symbols used in this index:

Nomenclature Lower case, Roman	Genera, species, and subspecies of bacteria. Every bacterial name mentioned in the *Manual* is listed in the index. Specific epithets are listed individually and also under the genus.*
CAPITALS, ROMAN:	Names of taxa higher than genus (tribes, families, orders, classes, divisions, kingdoms).
Pagination Roman:	Pages on which taxa are mentioned.
Boldface:	Indicates page on which the description of a taxon is given.†

* Infrasubspecific names, such as serovars, biovars, and pathovars, are not listed in the index.

† A description may not necessarily be given in the *Manual* for a taxon that is considered as *incertae sedis* or that is listed in an addendum or note added in proof; however, the page on which the complete citation of such a taxon is given is indicated in boldface type.
